Testing the movements of the wrist joint include positions that combine flexion-extension and radial-ulnar deviation. When there is a SLL injury, there is an increase of the scaphoid motion but not of the lunate motion that leads a change in the functional arc of wrist motion used in activities of daily living. The Watson test is a provocative test for detecting damage at the dorsal component of the SLL. The patient will have dorsal subluxation of the proximal scaphoid over the dorsal end of the radius while the wrist is radially deviated; the clinician will notice patient's painful click while doing the test (1).

Villiers (1998) showed that the dorsal ganglia of the wrist appear related with dorsal SLL defect with a communication between the ganglion and SLL.

In presence of severe trauma, the patient can present not only SLL injury but also with injuries to various ligamentous structures including the radiocapitate, radiotriquetral and dorsal radiocarpal ligaments or associated non-ligamentous injuries such as radial styloid fracture or scaphoid fracture.

Other diagnostic possibilities in a patient with dorsal wrist pain include: ulnar translocation syndrome, posterior interosseous nerve neuroma, physiologic scapholunate separation, distal radioulnar joint instability and triangular fibrocartilage complex tears.

Ulnar translocation syndrome occurs when the lunate is displaced in an ulnar direction. It is a frequent cause of radiocarpal instability. Although ulnar translation can be seen in advanced rheumatoid arthritis or in Madelung's deformity, abnormal translation of lunate in ulnar direction is pathognomonic of ulnar translocation syndrome. On X-ray, the lunate is positioned distal to the ulna and the distance between the radial styloid process and the scaphoid can be widened (type I) or normal (type II) with a gap between scaphoid and lunate. The patient presents with the carpus and hand offset in an ulnar direction.

Complementary imaging studies are essential to rule out the diagnosis of SLL damage (2). Dynamic radiographs or cineradiography are the first image choice. Radiographic features include widening of the space between scaphoid and lunate determined in PA view; a gap greater than 3-4 mm is considered to be pathologic (Image a). The width between scaphoid and lunate may also be considered abnormal when the midportion of the scapholunate joint space is larger than the capitulunate or third carpometacarpal joint space widths. Lateral view is important to demonstrate the scapholunate angle which should be less than 70°.

Osteoarthritis can be seen in long standing SLL damage. Initially the radio-scaphoid joint is involved but in advance stages various intercarpal joints can also be involved with the radiolunate joint being the last affected.

When radiographs do not clarify the diagnosis and the patient history and exam suggest a SLL injury, magnetic resonance (MRI) or MRI arthrography help in the treatment decision. Multi-detector CT arthrogram can demonstrate partial tears, abnormal angulations of the scaphoid and lunate bones, changes of the subchondral bone and abnormalities of the cartilage.

According to the Watson classification, there are three stages of scapholunate instability. Pre-dynamic instability, the first stage, is associated with partial SLL tear; although it can be symptomatic, it is not visible on radiographs. The second degree is dynamic scapholunate joint instability when there is a complete tear of the SLL and the third stage is scapholunate joint dissociation when secondary stabilizers are affected. This third stage can lead to degenerative changes with severe osteoarthritis of the wrist. A more detailed six stage classification of Elias et al that take in account prognostic factors that help to assess the probability of a positive post-surgical outcome.

Musculoskeletal ultrasound is helpful in the recognition of dorsal SLL abnormalities and in confirming SLL laxity by placing the probe longitudinal to the dorsal part of the SLL with the wrist in volar flexion while asking the patient to make fist.

1.d Treatment

Treatment should be tailored to each stage of involvement and include: arthroscopic debridement, reconstruction, tenodesis, wrist joint fusion or carpectomy in complete disruption with cartilage loss. (Images b and c) According to Elias et al (3), prognostic factors that may affect surgical outcome of SLL injuries include:

- An SLL tear affecting not only the dorsal portion but extending to the volar and/or fibrocartilaginous layers
- Intra-substance SLL tears are more difficult to heal than the osseous avulsion.
- Condition of the secondary stabilizers of the scapholunate joint.
- Ability to reduce the carpal misalignment.
- The integrity of the radiocarpal and metacarpal cartilages.

- Unfortunately, the level of evidence supporting these various techniques is generally low and does not completely answer questions about their efficacy.

IN-DEPTH DISCUSSION II

Trigger finger

INTRODUCTION

Trigger finger is a common disorder of the hand with an incidence of 2.6% in general population up to 10% in diabetic patients, with higher prevalence in the 6th decade. This disorder is characterized by snapping or locking of the flexor tendons in the affected finger, a phenomenon that generates pain during flexion and extension accompanied by mechanical dysfunction. It occurs more commonly in women, in the dominant hand and most often it affects the third, fourth finger or thumb.

Work activities which imply repetitive gripping of an item or sport activity (e.g. volley) may trigger this pathology but an important percentage of the cases are idiopathic. A tendon sliding deficit generated by a discrepancy between the tendon / sheath size and a hypertrophic A1 pulley underlies this pathology. Still, the pathogenesis is not completely understood and may be multifactorial. A fibrocartilaginous metaplasia of the A1 pulley seems to develop in idiopathic trigger finger with subsequent mismatch between the pulley and underlying tendons.

The most important risk factors are diabetes mellitus, rheumatoid arthritis, hypothyroidism, acromegaly, renal failure with or without amyloidosis and overweight.

Anatomy

The flexor tendon system of the hand consists of flexor muscles of the forearm and the tendinous extensions. At digital level, a specialized digital flexor sheath assures a smooth and rapid flexion of each finger. The flexor muscles of the digits belong to the anterior compartment of the forearm and include the flexor digitorum profundus (FDP), flexor digitorum superficialis (FDS) and the flexor pollicis longus (FPL).

The **FDP** muscle originates from the proximal, anteromedial aspect of the ulna and reaches the distal forearm as a single muscle belly but separates distally in a radial and ulnar bundle. At the musculo-tendinous junction, the radial bundle will form the flexor profundus of the index finger and the ulnar bundle will form the individual profundus tendons of the third, fourth and fifth fingers.

The index and third finger muscles are innervated by the anterior interosseous branch of the median nerve, roots C8 and T1. The ulnar nerve (motor branches, roots C8 and T1) provide innervation for the fourth and fifth finger muscles. The FDP muscles receive blood supply from the ulnar artery, anterior and common interosseous arteries.

The muscular contraction will initiate the flexion of the proximal interphalangeal joint (PIP) and the distal interphalangeal joint (DIP).

The **FDS** muscle originates (ulnar and radial head) from the anterior compartment of the forearm and is located superficial to FDP. At the level of the distal forearm it forms four distinct tendons displaced in 2 layers: superficial (FDS of the third and fourth finger) and profound (FDS of the second and fifth finger). Innervation is provided by the median nerve (roots C7, C8, T1). Blood supply is provided by the branches of the artery of the median nerve, muscular branches of the ulnar and radial arteries.

The **FPL** originates from the mid-anterior aspect of the radius and interosseous membrane. The muscle tendon inserts into the distal phalanx of the thumb and during contraction interphalangeal (IP) and metacarpophalangeal (MCP) joints are flexed. The interosseous branch of the median nerve is responsible for the innervation.

The digital flexor sheath protects the tendons and consists of a membranous and retinacular portion. The membranous portion (synovial lining), made of visceral and parietal layers surround the FDP and FDS and facilitates the smooth gliding of the structures during flexion and extension movements. The retinacular component displays annular, cruciform and transverse fibres forming a pulley system which overlie the membranous portion. Its function is to stabilize the tendons during finger flexion. The pulley system consists of the palmar aponeurosis pulley, 5 annular pulleys and 3 cruciform pulleys. A1 pulley consists of strong, rigid and non-extensible annular bands of connective tissue located at the level of the volar aspect of the metacarpophalangeal joint (MCPj) which are contiguous with the flexor tendon sheath. A1 pulley pathology generates trigger finger.

Clinical presentation

Pain and mechanical dysfunction occur at the base of the digit (volar aspect) during finger flexion attempts while gripping. During flexion, the smooth and rapid tendon sliding is replaced by a delayed, hesitated move of the affected finger, ending with a snap when closed and obstacle is overcome. During extension, a similar phenomenon occurs before the tendon snaps into full extension. In severe cases, the digit remains locked in a bent position and must be manually (passive move) reinstated in full extension or full flexion. With each movement, especially when performing demanding working tasks, the tendon becomes more irritated, inflamed and thicker, aggravating the local situation. The phenomenon is more pronounced in the morning or after a longer interval of finger inactivity (Figure 1).

Figure 1. During digits extension manoeuvre, the affected digit remains locked in a bent position.

Diagnosis

Diagnosis is made on clinical basis after collecting the medical history and performing a physical examination which consists of dynamic manoeuvres of active flexion and extension of the digits, identification of the areas where pain is expressed during motion.

Ultrasound evaluation is an extension of the clinical examination. It can easily help to depict soft tissue underlying lesions. In normal conditions, A1 pulley is depicted as a hypoechoic band superficial to the flexor tendon sheath. In axial plane, marginal shadow artefacts can be depicted because of anisotropy. The tendons (FDP and FDS) have a regular fibrillar structure and slide smoothly when performing dynamic examination (finger flexion).

The ultrasonographic hallmark findings in trigger finger pathology are: hypoechoic thickening of the A1 pulley, tenosynovitis, sometimes nodular thickening of the flexor tendons at dynamic examination (while sliding under the A1 pulley) (Figure 2a, b).

Figure 2a. Volar finger aspect at level of MCP joint, longitudinal scanning. P- A1 pulley (thickened, hypoechoic), FDP- flexor digitorum profundus tendon, FDS- flexor digitorum superficialis tendon. Synovial sheath distension (white arrow).

Treatment

The treatment options are conservative - immobilization, oral nonsteroidal anti-inflammatory drugs (NSAIDs), local US guided corticosteroids (CS) / hyaluronic acid derivate injections and surgical methods like open or percutaneous resection of A1 pulley.

Mild symptoms may benefit from simple measures like avoiding activities which require repetitive gripping, finger exercises in order to preserve mobility, NSAIDs, massage, night splints (rest and maintaining extension position) for some weeks. For moderate to severe symptoms and functional disability, several conservative or surgical options may help. NSAIDs may diminish pain and tendon swelling. Local injected CS (close to the tendon sheath or strictly inside the tendon sheath) may reduce the inflammation and restore the finger movements (Fig 3 a, b). Maximum of efficacy is obtained in early phases when structural tendon and pulley damage is not so evident. In subjects affected by diabetes mellitus, rheumatoid arthritis refractory symptoms imply the repetition of CS injections. Surgical options may be a solution in trigger finger refractory to conservative methods.

Generalized pain syndromes

- Including fibromyalgia and chronic fatigue syndrome -

Piercarlo Sarzi-Puttini, Françoise Laroche, Serge Perrot

A previous version was coauthored by Françoise Laroche, Serge Perrot, Lucy Coates, Ernest Choy

LEARNING OBJECTIVES

- To describe the epidemiology of generalised pain syndromes—in particular, fibromyalgia and chronic fatigue syndrome (CFS), and their impact on patients, healthcare systems and society
- To recognise and diagnose generalised pain syndromes—in particular, fibromyalgia and CFS
- To select appropriate investigations to exclude differential diagnoses
- To describe and explain the pathophysiological processes that underpin these syndromes and explore their implication on research and clinical practice—in particular, for fibromyalgia and CFS
- To manage patients with generalised pain syndromes—in particular, fibromyalgia and CFS
- To outline recent advances in the diagnosis and management of fibromyalgia syndrome

1 Introduction

Interest in chronic widespread pain has increased considerably in the past decade. Pain has been shown to be the most common reason for medical consultations in the general population. At least 50% of these patients have musculoskeletal pain, which reflects the relevance of this health problem. For the musculoskeletal diseases among these patients, non-articular rheumatic pain syndromes are a major component. These conditions can be regional or generalised. Regional conditions include tendonitis and bursitis, neurovascular entrapment, flatfoot and regional myofascial pain syndromes. Generalised conditions include multiple bursitis–tendonitis syndrome, fibromyalgia and chronic fatigue syndrome (CFS). Multiple bursitis and tendonitis syndrome presents with multiple anatomically localised areas of pain and dysfunction but fibromyalgia tender points are absent. It is likely to respond to local injection therapy. Fibromyalgia and CFS are associated with chronic widespread pain, which results in significant disability and has a major impact on quality of life. They are a major burden on the healthcare system and society. The former chief medical officer in the UK, Professor Liam Donaldson, wrote to all UK doctors highlighting the problem and emphasising the need for more information for doctors and patients.

Fibromyalgia syndrome (FMS) is one of the most common causes of chronic widespread pain. It is characterised by reduced pain thresholds (hyperalgesia) and pain with normally innocuous stimuli (allodynia). Diffuse pain is often accompanied by a wide range of symptoms, including fatigue, sleep disturbance, functional impairment, cognitive dysfunction, variable bowel habits, depression, stiffness and more. One-third of patients with FMS experience significant depression or anxiety. FMS shares many common features, and often coexists, with other syndromes such as CFS, irritable bowel syndrome (IBS), and dysmenorrhoea, leading to the suggestion that it is part of a spectrum of disorders characterised by central sensitisation (Clauw, 2014). FMS also often occurs concomitantly with other conditions, such as rheumatoid arthritis and systemic lupus erythematosus, and other chronic pain syndromes, such as low back pain and headaches. In such cases, the unwary clinician may instigate inappropriate treatment (Atzeni *et al*, 2011). In the past, this has been referred to as secondary FMS, suggesting that these conditions predispose patients to develop FMS. However, this has not been used recently as the precise relationship between FMS and these chronic painful conditions remains unclear.

2 History of FMS

FMS is not a new disease. Froriep described hard places in the muscles of patients with 'rheumatism' which were painful to pressure in 1850 (Froriep, 1850). In 1904, Gowers first coined the term 'fibrositis' in patients who complained of pain on light touch and had fatigue and sleep disturbances in the absence of any signs of local or systemic inflammation. Lewis and Kellgren, in the 1930s, injected hypertonic saline into deep muscle tissue and described referred muscle pain (Kellgren, 1938; Lewis, 1938). Subsequently, fibrositis was

considered a common cause of muscular pain, although many clinicians thought of it as 'psychogenic rheumatism'. The term 'fibromyalgia' was introduced in 1976 by Hench (1976).

In 1977, Smythe and Moldofsky first showed that certain anatomical locations were more tender in patients with FMS than in controls. These 'tender points' were often identical to those points most tender in regional pain conditions such as 'tennis elbow', 'costochondritis' and cervical strain syndromes. Their seminal work has formed the basis of the current classification/diagnostic criteria for FMS. Subsequently, many studies have confirmed the diagnostic utility of tender points, leading to several proposed diagnostic criteria based on presence of pain and tender points, with or without supplementary symptoms, after excluding other rheumatic or systemic diseases. In 1990, the American College of Rheumatology (ACR) criteria for the classification of FMS were published based on comparing patients with age- and sex-matched controls (Wolfe *et al*, 1990). The criteria require the presence of chronic widespread pain, defined as bilateral, above and below the waist, and axial, for at least 3 months and the presence of at least 11 out of 18 tender points. While the primary objective of the ACR classification criteria was to facilitate research so that homogeneous populations of patients could be studied, it is commonly applied in routine practice for diagnosis.

3 Clinical features

3.1 Pain

The most common presenting complaint of patients with FMS is 'pain all over their body', though the severity of pain may vary between patients. Often it fluctuates from one area to another. In some patients, there is a history of chronic regional pain before developing more widespread pain. Pain is often described as a chronic ache with occasional severe sharp spasm or electric shock. Paraesthesia is common. Some patients describe their muscles as tense and 'tied in knots'. Pain is often made worse by exertion or physical activities, although many patients also complain of spontaneous pain without any obvious precipitating factor. Simple analgesics such as paracetamol or non-steroidal anti-inflammatory drugs (NSAIDs) are rarely effective (Clauw, 2014).

One of the characteristic features of FMS is 'tenderness'. Patients often complain that even light touch or pressure is painful: hyperalgesia and allodynia. Hyperalgesia is excessive severe pain induced by a noxious stimulus. Allodynia is defined as the perception of pain induced by an innocuous stimulus. Some patients complain that the slightest touch can make them recoil in pain. Many patients also have a history of other chronic painful conditions such as migraine, non-cardiac chest pain, heartburn, dysmenorrhoea and IBS.

Often patients have severe pain which is disabling. They cannot manage routine household chores, especially shopping and cleaning, and those in employment often find difficulty in coping with work.

Although patients with CFS often complain of chronic widespread pain, it is not universal. Presence of pain is not an obligatory factor for the diagnosis of CFS.

3.2 Fatigue

Fatigue affects 80–90% of patients with FMS. It ranks second after pain as the most disabling symptom by many patients. The severity of fatigue varies but, in general, it is less disabling than in CFS. Patients often describe feeling ‘overwhelming tiredness’ and ‘completely washed out’. Severe attacks may come on suddenly. Some patients find it more difficult to cope with than pain since rest and sleep rarely improve fatigue. When fatigue is overwhelming and the muscular pain less prominent a diagnosis of CFS should be considered (Clauw, 2014; Dailey *et al*, 2014).

3.3 Non-restorative sleep

Over 70% of patients with FMS have poor quality of sleep and do not feel ‘refreshed’ in the morning. Patients often associate poor sleep quality with feeling tired and difficulty in performing physical activity. In addition, some patients with FMS are sleepy during the day. Other patients may have difficulty in getting to sleep or they wake up frequently during the night. Impaired sleep quality was found to be predictive of pain, fatigue and social functioning in one study. Polysomnography has found correlation between sleep disturbance with specific patterns of alpha intrusion and phasic alpha sleep activity. Concomitant restless leg syndrome occurs in 20–40% of patients with FMS. Loud snoring and disturbances of breathing during the night are uncommon in FMS, and the presence of these symptoms should alert clinicians to possible primary sleep disorders, such as obstructive sleep apnoea syndrome (Clauw, 2014).

3.4 Depression and anxiety

Mood disturbance is common in FMS. The prevalence of depression and anxiety in FMS is much higher among patients who attend secondary care (70–80%) than among those in the community (30–50%). Many patients who present to hospital outpatient clinics have a history of depression or anxiety, leading to the view that mood disorders are the cause of FMS. However, mood disorder is not universal and response to antidepressants in patients with FMS has been shown to be independent of any change in mood (Arnold *et al*, 2007). Generalised anxiety seems more common in FMS than depression, and seems to be associated with the distress of the patients with medically unexplained symptoms and chronic pain. This suggests that although depression or anxiety may be the cause of FMS in some patients, it is not the sole pathogenic factor and fibromyalgia cannot be presented as a psychogenic pain condition and masked depression. Patients with depression often have severe fatigue and poor sleep quality. Patients with anxiety often have palpitation and dizziness, sweating, and paraesthesia. In severe cases, some patients may experience panic attacks (Arnold *et al*, 2007; Goesling *et al*, 2013).

3.5 Impaired cognition

Patients with FMS often describe having a 'brain fog,'—that is, cognitive impairment which includes problems with memory, an inability to focus on tasks, retain new information, do mental arithmetic or solve problems. Typically these periods are episodic and last for a few days, although in some cases they may be more prolonged. Impaired cognition is associated with problems coping with work, especially in those patients for whom employment is mentally demanding. It is a major contributor to frustration and psychosocial stress (Clauw, 2014; Dailey *et al*, 2014).

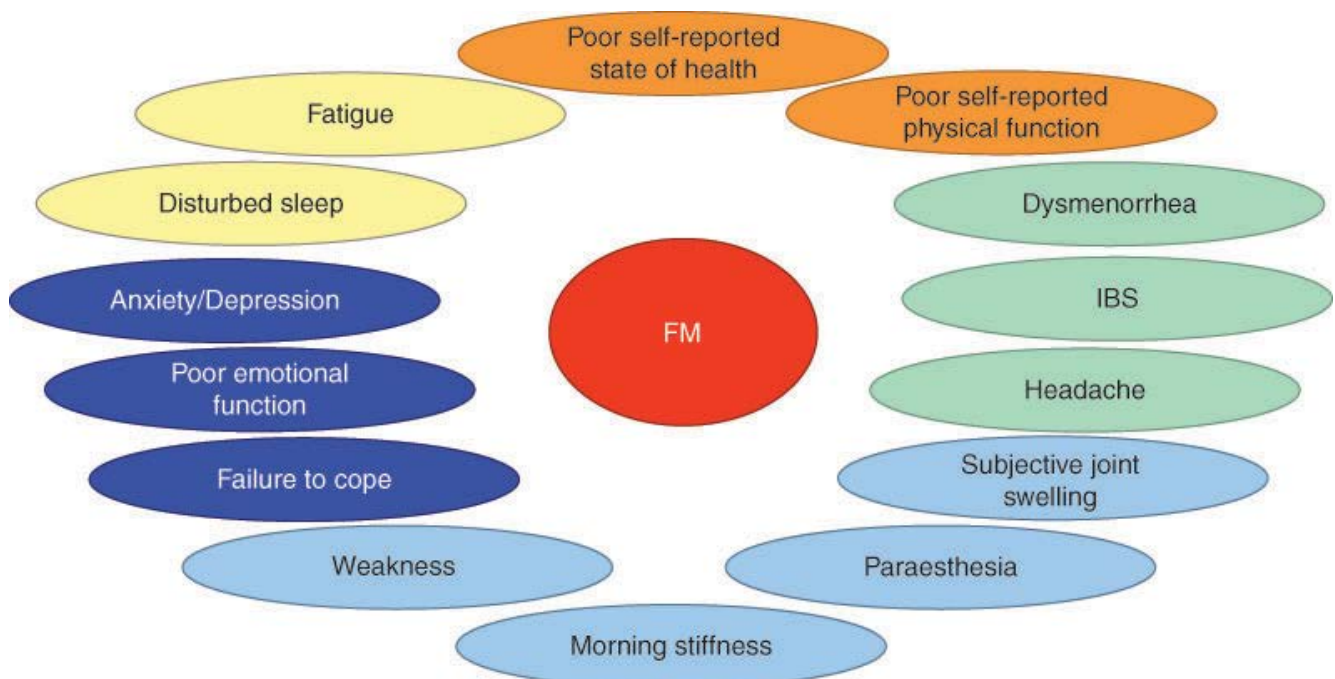

3.6 Morning stiffness

Prolonged early morning stiffness is common in patients with FMS. The duration is variable. For the unwary clinician, it may lead to diagnostic confusion with inflammatory arthritis, especially in those patients with FMS who also have swollen hands or feet. In FMS, stiffness is often not relieved by exercise and objective evidence of synovitis is also lacking.

3.7 Other symptoms

Other common symptoms in FMS include nausea, vomiting, bloating, abdominal pain, diarrhoea and constipation. Concomitant diagnosis of IBS is very common. Uro-gynaecological symptoms are also common, especially urgency, frequency, incontinence, pelvic pain and dysmenorrhoea (figure 1).

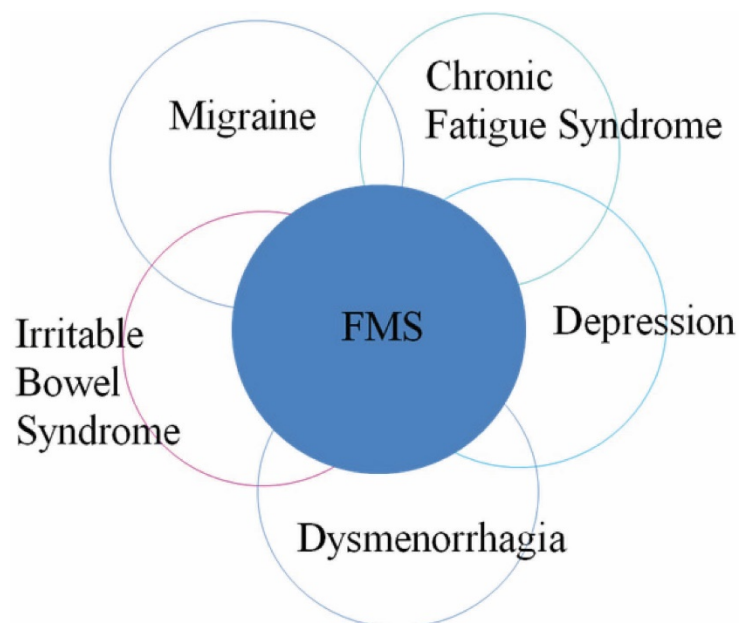

Figure 1 Symptoms associated with fibromyalgia (FM) syndrome. IBS, irritable bowel syndrome.

3.8 Associated conditions and dysfunction syndromes

Psychiatrists have called one group of disorders 'affective spectrum disorders', which often coexist. These include FMS, IBS, CFS, depression and anxiety disorders, and migraine (figure 2), which are all associated with psychological distress. It has been thought that depression may lead to the development of widespread pain, and although it is commonly reported in FMS, it is equally likely that chronic pain results in depression as most patients do not have any psychiatric illness. Furthermore, depression can be treated without improving the pain state. In pain classification, pain states such as fibromyalgia, IBS, CFS and temporomandibular disorders, are included in dysfunctional pain syndromes, characterised by abnormal central sensitisation and pain modulation deficiency.

Figure 2 *Overlap with somatisation disorders. FMS, fibromyalgia syndrome.*

Estimates of the prevalence of IBS in patients with FMS range from 30% to 35% to as high as 70%. A high frequency of FMS was documented in patients with chronic fatigue seen in a primary care practice. Seventy per cent of patients with chronic fatigue had persistent diffuse musculoskeletal pain and the results of their tender point examinations were similar to those of patients with FMS. Clauw (2014) reported that the symptoms of interstitial cystitis and FMS significantly overlap and that patients with interstitial cystitis have diffuse pain, which also is seen in FMS. Fifty-seven per cent of 77 patients with FMS had clinically significant levels of post-traumatic stress disorder. Finally, 22% of female patients with migraine had concomitant FMS (Hausteiner-Wiehle and Henningsen, 2014).

3.8.1 Chronic fatigue syndrome

CFS is also known as myalgic encephalomyelitis, post-viral fatigue syndrome and chronic fatigue immune dysfunction syndrome. Although fatigue is the dominant clinical feature in CFS, there is significant overlap

between CFS and FMS. Patients with CFS and FMS often report similar symptoms, such as pain, fatigue, mood disturbance, cognitive impairment, poor sleep quality and increase in multiple chemical sensitivities (Brown and Jason, 2007). Seventy per cent of patients with FMS and 30% of those with multiple chemical sensitivities met the criteria for CFS. In contrast to FMS, abrupt onset of symptoms is common in CFS, usually preceded or accompanied by a viral or flu-like illness. In many patients, CFS may be precipitated by stress, although the role of infection or stress in its development remains controversial. Some patients with CFS have a gradual onset, and mimic FMS. Features, which are common in CFS, but less so in FMS, include general malaise or influenza-like symptoms, such as sore throat and painful lymph nodes without lymphadenopathy.

As mentioned above, patients often report getting a flu-like or upper respiratory tract infection, from which they seem never to fully recover and, consequently, develop CFS. Hence, the name post-viral fatigue syndrome. However, in some patients, the development of CFS may be preceded by severe adverse stress in the preceding months (Adamowicz *et al*, 2014).

There is no assay or pathological test for CFS; diagnosis is based on symptoms and exclusion of other illnesses. There are many sets of diagnostic criteria for CFS (Bates *et al*, 1994). In general, they include the presence of fatigue which is chronic and/or recurrent for >6 months, which results in substantial reduction in activity, is worsened by exertion and is unexplained by other conditions. Some of these criteria include other symptoms of CFS, such as sore throat, muscle pain, cognitive dysfunction, tender lymph nodes, chemical hypersensitivity, headache and unrefreshing sleep. Exclusion criteria include psychotic, melancholic, or bipolar depression, psychotic disorders, dementia and anorexia or bulimia nervosa.

3.8.2 Differentiating CFS from FMS

Medical opinions are split on relationship between these two conditions. They are similar, and share many clinical features. Some believe the two conditions are the same, while others view them as different. Differentiating the two can be difficult in some patients but the following are helpful. First, pain is the predominant problem in people with fibromyalgia, whereas fatigue is the major complaint in people with CFS. The latter is usually severe and often completely incapacitating. Second, an abrupt onset preceded by a viral infection is more typical of CFS than FM. Third, the presence of sore throat or enlarged or tender lymph nodes would also suggest CFS.

The management of FMS and CFS is similar. Education, exercise and low-dose antidepressant drugs are used to treat both conditions.

4 Diagnosis of FMS

It is important to exclude other rheumatic diseases when assessing a patient who may have FMS (Cazzola *et al*, 2008). Distinguishing patients with FMS from those with early rheumatoid arthritis or connective tissue

diseases may be difficult. Unexplained weight loss or gain and fever are symptoms that strongly suggest alternative diagnoses. Physical examination of patients with FMS is often normal except for the presence of pain on movement and tender points. However, it is important to ensure patients do not have any evidence of synovitis, limitation in passive joint movement, skin rashes or muscle weakness.

There is no specific diagnostic laboratory test for FMS so blood tests are used to exclude alternative diagnoses. In general, full blood count, biochemistry, erythrocyte sedimentation rate or C-reactive protein and thyroid function tests are all that are necessary. Rheumatoid factor and antinuclear antibodies are typically negative and their determination is not warranted unless the clinical suspicion of rheumatoid arthritis or connective tissue disease is high. Weakly false-positive rheumatoid factor and antinuclear factor are common in normal people and could mislead the unwary. Virological serological tests are usually unhelpful, even in CFS, and are not indicated routinely. They should be considered only when active infection is suspected owing to clinical features such as fever. Similarly, Lyme disease serology is not routinely necessary (Cazzola *et al*, 2008).

Differential diagnoses of FM include osteomalacia, hypermobility syndrome, primary generalised osteoarthritis, polymyalgia rheumatica, rheumatoid arthritis, connective tissue diseases such as systemic lupus erythematosus, Sjögren's syndrome and inflammatory muscle diseases, myopathies, hypothyroidism and malignancies (Atzeni *et al*, 2011).

4.1 1990 ACR classification criteria

The 1990 ACR classification criteria for FMS were developed initially to facilitate research by identifying homogeneous groups to enable results from different studies to be interpreted. They stipulate that essential factors are a history of widespread pain lasting for more than 3 months, defined as pain in both sides of the body, pain above and below the waist. In addition, axial skeletal pain (cervical spine, anterior chest, thoracic spine or low back) must be present. Low back pain is considered lower segment pain. Pain must be present in at least 11 of 18 tender point sites on digital palpation with an approximate force of 4 kg (until the colour under the nail blanches) (figure 3). These must be reported as 'painful' not just 'tender'. The classic tender points of FMS are distributed symmetrically over the occiput, low cervical, trapezius, supraspinatus, second rib, lateral epicondyle, gluteus, greater trochanter and at the medial fat pad of the knee (figure 3). Each point is palpated with the thumb of the examiner, using gradually increasing pressure, until the patient reports the pressure to be painful. A point is considered 'positive' if pressure <4 kg evokes pain by this procedure (Wolfe *et al*, 1990).

Figure 3 Tender point locations for fibromyalgia: occiput; low cervical; trapezius; supraspinatus; second rib; lateral epicondyle; gluteus; greater trochanter; knee.

Box 1 ACR 2010 fibromyalgia diagnostic criteria

Criteria

A patient satisfies the diagnostic criteria for FMS if the following 3 conditions are met:

1. WPI ≥ 7 and SSS score ≥ 5 or WPI 3–6 and SSS score ≥ 9 .
2. Symptoms have been present at a similar level for at least 3 months.
3. The patient does not have a disorder that would otherwise explain the pain.

Ascertainment

WPI

Note the number of areas in which the patient has had pain over the past week (score will be between 0 and 19): left shoulder girdle, right shoulder girdle, left hip (buttock, trochanter), right hip (buttock, trochanter), left jaw, right jaw, upper back, lower back, left upper arm, right upper arm, left lower arm, right lower arm, left upper leg, right upper leg, left lower leg, right lower leg, neck, chest, abdomen.

SS scale score:

1. Fatigue, waking unrefreshed, cognitive symptoms. For each of the 3 symptoms above, indicate the level of severity over the past week using the following scale: 0, no problem; 1, slight or mild problems, generally mild or intermittent; 2, moderate, considerable problems, often present or at a moderate level or both; 3, severe, pervasive, continuous, life-disturbing problems.
2. Considering somatic symptoms in general, indicate whether the patient has 0, no symptoms; 1, few symptoms; 2, a moderate number of symptoms; or 3, many symptoms.

The SSS score is the sum of the severity of the 3 symptoms (fatigue, waking unrefreshed, cognitive symptoms) plus the extent of somatic symptoms in general. The final SSS score is between 0 and 12.

FMS, fibromyalgia syndrome; SSS, Symptom Severity Scale; WPI, Widespread Pain Index.

4.2 Controversy about the diagnosis of FMS

Although the 1990 ACR criteria were useful for providing homogeneous populations for research and clinical trials, there is significant controversy about the diagnosis of FMS. Some clinicians have argued that FMS is not a distinct disease entity. There is a belief that labelling patients with FMS encourages chronic illness behaviour and increases healthcare use (Hadler and Ehrlich, 2003). However, recent research in the UK showed the contrary to be true. Using the General Practice Research Database, Hughes *et al* have shown that healthcare use among patients with FMS was already very high in the 8 years preceding the diagnosis (Hughes *et al*, 2006*). Interestingly, healthcare use decreased after diagnosis, indicating that diagnosis could be used constructively to reassure and educate patients. A screening test (Perrot *et al*, 2010) (FiRST—Fibromyalgia Rapid Screening Tool) has been developed to detect FMS among patients with chronic widespread pain, based on a list of six questions, with five positive answers detecting FMS with a sensitivity and specificity of more than 80%.

Furthermore, research using neuroimaging to study patients with FMS has shown specific patterns in the brain, associated with central sensitisation. Both single photon emission computed tomography (SPECT) and functional magnetic resonance imaging (fMRI) have demonstrated reduced thalamic blood flow under resting conditions and also shown that when a pressure stimulus is applied to the thumb nail, responses of patients with FMS in the pain-processing regions of the brain occur at much lower stimulus intensities than in healthy controls (Gracely *et al*, 2002*). Such objective studies showed conclusively that pain is ‘real’ in FMS and further support the diagnosis of FMS.

4.3 Survey base criteria for FMS

Recently, the ACR published survey base criteria for FMS, and a further modified version was published in 2011 (Wolfe *et al*, 2011). The preliminary ACR 2010 criteria for the diagnosis of FMS do not require physical examination, but the requirement for the presence of widespread pain for at least 3 months and that the patient does not have a disorder that would otherwise explain the pain are retained. However, tender point count has been replaced by a symptom checklist which includes the Widespread Pain Index (WPI) and Symptom Severity Scale (SSS). They are now modified with the 2010 modified FM diagnostic criteria available (Wolfe *et al*, 1997*; Wolfe, 2009*; Wolfe *et al*, 2010*; Wolfe, 2011*), see box 1.

In the WPI, patients are asked to indicate the regions (maximum 19 regions) of the body in which pain has been experienced during the past week. Each positive region is given a score of 1 (WPI ranges from 0 to 19).

SSS is the sum of the severity of the three symptoms (fatigue, waking unrefreshed, cognitive symptoms) plus the extent (severity) of somatic symptoms in general. Each of these three symptoms is scored between 0 and 3 (0 = no problem, 1 = slight or mild problems, generally mild or intermittent, 2 = moderate, considerable

problems, often present and/or at a moderate level, 3 = severe: pervasive, continuous, life-disturbing problems over the past week). The extent of somatic symptoms is also scored between 0 and 3 (0 = no symptoms, 1 = few symptoms, 2 = a moderate number of symptoms and 3 = many symptoms). Permissible somatic symptoms include muscle pain, IBS, fatigue/tiredness, thinking or remembering being a problem, muscle weakness, headache, pain/cramps in the abdomen, numbness/tingling, dizziness, insomnia, depression, constipation, pain in the upper abdomen, nausea, nervousness, chest pain, blurred vision, fever, diarrhoea, dry mouth, itching, wheezing, Raynaud's phenomenon, hives/welts, ringing in ears, vomiting, heartburn, oral ulcers, loss of/change in taste, seizures, dry eyes, shortness of breath, loss of appetite, rash, sun sensitivity, hearing difficulties, easy bruising, hair loss, frequent urination, painful urination and bladder spasms. The final SSS score is between 0 and 12.

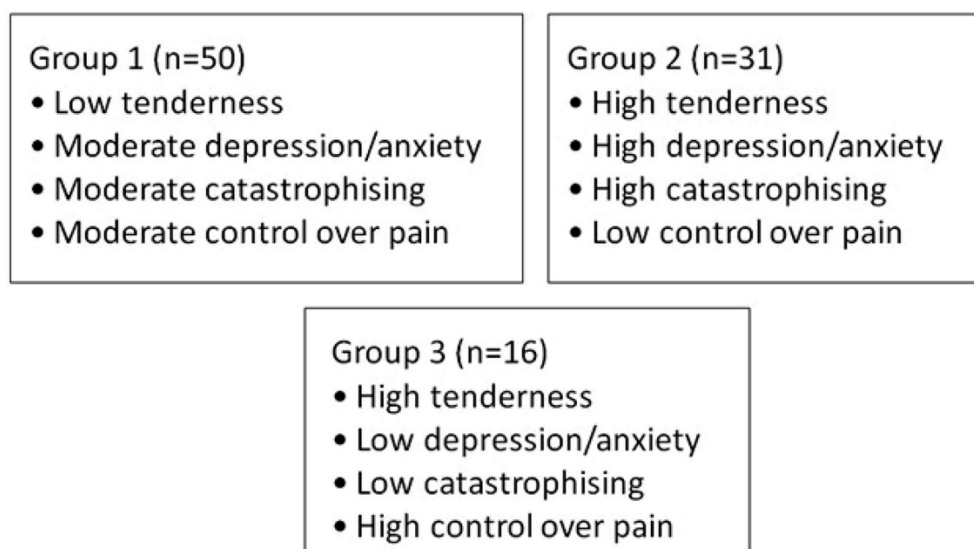

A patient satisfies the criteria for FMS if the following conditions are met: WPI >7 and SSS score >5 or WPI 3–6 and SSS score >9.

Removing the reliance on tender point count is the major advantage of the survey base criteria for FMS. In addition the SSS includes characteristic features of FMS and may be used to monitor disease activity. These criteria are not intended to replace the ACR 1990 classification criteria, but to represent an alternative method of diagnosis.

4.4 Subtypes of FMS

FMS is not a homogeneous condition. Although chronic widespread pain and increased tenderness are universally present, other associated symptoms may not be present in all patients. A study by Giesecke *et al* using cluster analysis suggested that there may be three different subtypes (figure 4) (Giesecke *et al*, 2003*):

Figure 4 Different subgroups of fibromyalgia suggested by Giesecke *et al*. (Reproduced with permission from Giesecke *et al*, *Arthritis Rheum* 2003;48:2916–22*.)

1. Moderate anxiety, depression, catastrophising and poor control of pain, the highest pain thresholds and low tenderness;
2. High levels of anxiety, depression and catastrophising, low pain control and considerable tenderness;
3. Low levels of anxiety, depression and catastrophising, good control of pain but very low pain threshold and the most tenderness.

Another classification shows that patients with FMS can be classified according to the type of pain and sensory profile, and comorbidities (Rehm *et al*, 2010).

In this study, the first subtype was the most common with over half the patients within this group, and therefore was considered to represent 'typical FMS'. It is important to note, however, that the patients in this study were recruited from the community. The proportion of patients in each subtype might change if patients in secondary care were studied since the latter tends to include patients with a higher prevalence of mood disturbance and psychosocial stress.

5 Epidemiology

5.1 Prevalence

Chronic widespread pain is common. The definition of chronic widespread pain according to the 1990 ACR criteria provided uniformity and standardisation for comparing outcomes of prevalence studies around the world. Epidemiological studies reported comparable prevalence rates of chronic widespread pain in the UK, Canada, Israel, United States and Sweden (Neumann and Buskila, 2003). These rates range from 7.3% to 12.9%. This can be compared with chronic regional pain, such as low back pain, which affects 20–25% of the population. Both conditions are more common in women with a female to male ratio of 1.5. In population studies psychosocial distress is associated with the subsequent development of chronic widespread pain (Gupta *et al*, 2007).

In France, using the FiRST screening tool, FM prevalence has been estimated to be 2% of the adult population.

5.1.1 Determination of the epidemiology of fibromyalgia

Several epidemiological studies have examined the prevalence of FMS in North America and Europe—for example, DEFI (Détermination de l'Epidémiologie de la Fibromyalgie) (Perrot *et al*, 2011). The prevalence of FMS in the general population was reported to range from 0.5% to 5% (White *et al*, 1999). In the USA Wolfe *et al* estimated the prevalence of FMS to be 2% overall (3.4% in women and 0.5% in men). In these epidemiological studies patients with chronic widespread pain are identified by pain without determining the presence or absence of 11 out of 18 fibromyalgic tender points which is stipulated by the ACR criteria. In

Europe a population-based epidemiological study, the Feel study (Fibromyalgia Epidemiology European Large-scale survey), found a point prevalence of 7% and 10% in France and Portugal, respectively (Wolfe *et al*, 1995*). FMS is more common in women. In hospital-based studies the female to male ratio was 7:1. In the general population the ratio is 3:1. The incidence of FMS is highest in those aged 20–55 years, but the condition may occur at any age, including childhood. The prevalence of FMS increases with age, reaching 7% in women aged 60–80 years.

The common association of FMS with other pain syndromes, other rheumatic disorders, chronic viral infections and systemic illnesses has been well documented in several studies. The prevalence of FMS in outpatient clinics is much higher than in the general population and ranges from 10% to 16% in rheumatology outpatient clinics. Among patients hospitalised on internal medicine wards, 62% reported musculoskeletal pain, 36% reported chronic regional pain, 21% reported chronic widespread pain and 5% reported transient pain. Fifteen per cent of all the patients had FMS, most of whom (91%) were women.

There are limited data on the prevalence of CFS which is thought to be around 0.4–0.5%, much less than for FMS. It is more common in female subjects and can affect children as well as adults (Branco *et al*, 2005).

5.2 Risk factors

Many studies have shown that psychological conditions, such as somatisation, having a mental disorder, presence of psychological distress, major depression, generalised anxiety, panic disorder and familial major mood disorder, are risk factors for developing FMS. In addition to genetic associations, various external stimuli such as infection, hormonal changes, physical trauma and stress (acute or persistent) have been temporarily associated with the development of FMS (Devanur and Kerr, 2006). McLean *et al* (2005) critically reviewed the literature on motor vehicle collision injury and FMS, using consensus standards developed by the ACR Environmental Disease study group. They concluded that the evidence that motor vehicle collision trauma may trigger FMS meets established criteria for determining causality (Buskila *et al*, 2008).

5.3 Impact on general health and quality of life

FMS varies in severity. However, quality of life in almost all patients with FMS is reduced. Both impaired physical function and emotional impact adversely affect the quality of life of patients with FMS. About 50% of all patients have difficulty with routine daily activities while 30–40% have to stop work or change their employment (Berger *et al*, 2007). The lack of support from family, friends and healthcare system may further compound the problem. Comparison has been made between patients with FMS and other rheumatic diseases, such as rheumatoid arthritis and osteoarthritis, using the Short Form-36. All eight components of the Short Form-36: physical functioning, physical role, social functioning, bodily pain, general health, vitality, emotional role and mental health scores, were significantly lower in patients with rheumatoid arthritis,

osteoarthritis and FMS than in normal healthy controls. Patients with FMS had significantly lower mental health scores than patients with rheumatoid and osteoarthritis (Picavet and Hoeymans, 2004).

5.3.1 Impaired physical function

Physical function is usually impaired in patients with FMS. Most patients reported some disability. They often have difficulty in performing daily activities. Getting going in the morning is often difficult in those patients with early morning stiffness. They require more time to get started and often struggle with tasks that require sustained or repetitive physical effort. Pain prevents them from lifting heavy objects and they often drop things because of poor grip. Walking is often affected. Many patients find their mobility and walking distance reduced. Fear of movement is common and patients often perceived higher ratings of exertion than normal during exercise.

5.3.2 Reduced mental health

As stated above, a major contributor to reduced quality of life in patients with FMS is poor mental health. One study compared the quality of life and general health status of patients with FMS with that of healthy volunteers using the Nottingham Health Profile. Patients with FMS had significantly higher Nottingham Health Profile scores, indicative of poorer general health status. Nottingham Health Profile scores correlated with disease activity as measured by tender point count, Fibromyalgia Impact Questionnaire (FIQ) and Health Assessment Questionnaire score. Patients with depression tended to have a higher Nottingham Health Profile score. This suggested an important relationship between pain, depression and quality-of-life scales in patients with FMS. Moreover, the Nottingham Health Profile score correlated with disease duration, suggesting that chronicity may adversely affect general health and quality of life. A study in Spain based on patients attending a university hospital found that poor quality of life is associated with having a greater number of children, fatigue and depression and a lower self-rated health. Interestingly, the number of specialists consulted before the diagnosis of FMS was associated with a poor quality of life, suggesting that delay in the diagnosis of FMS may adversely affect outcome. Prompt diagnosis and positive management may prevent the development of a vicious cycle leading to the condition spiralling out of control (Castelli *et al*, 2012).

5.3.3 Prognosis

In general, FMS is a long-term chronic illness. Most studies have shown that treatment can significantly improve symptoms, function and quality of life in the short term. The outcome of FMS, in general, is better in children than adults. Prospective long-term outcome studies based in tertiary hospitals in America and Europe found no significant change in disease over a 6–8-year period. Severity of pain, fatigue, disability and quality of life remained unchanged. Furthermore, they found little improvement in health status, health service use and costs, with about 25% of patients with FMS receiving disability or other compensation payments. Health status

as measured by Short Form-36 in patients with FMS is at least as poor, if not worse, than in those with other musculoskeletal diseases such as rheumatoid arthritis and osteoarthritis. Predictors of poor outcome include a history of major disturbing life event or severe disability. However, patients with FMS in the community may have milder conditions and better prognosis than those seen in specialist units.

Because spontaneous remission in FMS is rare, most patients will have a chronic illness. Educating patients to understand they have a chronic illness is important. However, they should be encouraged to adopt a positive attitude and, with the help of healthcare professionals, develop more effective coping strategies to manage their illnesses. Studies have shown that having a positive attitude and an effective coping strategy are associated with better outcome. Different studies have shown that patients with FMS who exercise regularly have a better outcome (Hauser *et al*, 2010). Resolution of stress and promotion of the patient's self-efficacy for control of pain are of pivotal importance in maintaining long-term improvement. Given the absence of a universal panacea, a multidisciplinary approach will be necessary to manage FMS, especially in patients with more severe or a wide range of symptoms. Conversely, a negative approach and over-reliance on medication may lead to excessive self-medication, alcohol or drugs.

5.4 Prognosis in CFS

Prognosis in CFS is similar to that for FMS. Less than 10% of patients experience full remission. Most cases are chronic, although with treatment there is some improvement over time. A study in 2001 found a higher incidence of violent deaths, including suicide and accidents, among people with chronic widespread pain (Gilson, 2001).

5.5 Healthcare burden

Different costs studies have been done among countries (White *et al*, 2002; Annemans *et al*, 2008). In Europe, the direct medical cost of FMS in 2004 was €5241 per patient compared with €2373 in ankylosing spondylitis. In America, the annual total healthcare cost of FMS in 2006 was \$9573 per patient compared with \$3291 in patients without FMS. Secondary care costs, hospitalisation and day care services were the main contributors. In 1997 data from the National Centre for Chronic Disease Prevention and Health Promotion in the USA showed that 7440 hospitalisations were due to FMS. It accounts for 2.2 million ambulatory care visits, 1.8 million physician office visits, 266 000 emergency department visits and 187 000 outpatient department visits. The average patient with FMS makes 10 primary care appointments a year and is admitted to hospital, on average, once every 3 years. The main component of direct medical cost in primary care clinics is diagnostic tests. Patients with FMS are more likely to be referred to hospital specialists and have diagnostic tests. Confronted by such statistics the former chief medical officer in the UK wrote to all the doctors in the UK emphasising the healthcare burden of chronic widespread pain, and urging more research and education to deal with the problem and improve outcome.

The UK General Practice Research Database, a large database covering 5 million patients in primary care, found that healthcare use by patients with FMS was already very high compared with that by disease controls, matched according to diagnosis date, gender and age, up to 10 years before diagnosis. Increased cost was due to a higher rate of referral, clinic visits, prescriptions and diagnostic tests. Patients with FMS averaged 25 visits and 11 prescriptions a year compared with 12 visits and 4.5 prescriptions a year in controls. Following the diagnosis of FMS, the referral rate declined considerably and the number of diagnostic tests and clinic visits stabilised and then declined to 13 per 100 patient-years 4 years after diagnosis. Therefore, the diagnosis of FMS can be used constructively to reduce healthcare expenditure. Modelling based on these data suggests that the diagnosis of FMS can save the healthcare system €200 per patient per year.

5.6 Societal cost

In addition to the direct medical cost of FMS, there are also significant indirect medical costs. Often patients with FMS have to change their work pattern or nature to continue in employment. In North America, 42% of patients with FMS were working and 28% were home-makers. The number of short-term disability days in patients with FMS was 16 compared with seven in patients without FMS. Total annual costs for fibromyalgia claimants were more than twice as high as the costs for the typical insurance beneficiary. Twenty to thirty per cent of patients were receiving disability payment and 16% were receiving social security benefits. In the USA the indirect medical cost per person-year in 1997 amounted to \$3671. The estimated overall annual cost of FMS in the USA is over \$9 billion. It accounts for a loss of 1–2% of the nation's overall productivity. In Europe, a study in the Netherlands reported that average annual indirect medical cost for FMS was €2573 per patient-year. Based on this the estimated total cost of FMS in Netherlands is almost €1 billion a year. In France and Germany total costs were estimated to be around €7000 per patient-year with a higher cost as FM severity increased.

6 Pathophysiology and pathogenesis of FMS

6.1 Perception of pain

6.1.1 History of pain models

Our understanding of pain has made significant advances over the past 20 years. Acute pain is an important protective mechanism and is linked to the stress response and reflex withdrawal to protect from further harm. Excessive tissue damage occurs if pain perception is absent as occurs in Charcot joints. Consequently, pain is inherently perceived as unpleasant, resulting in psychological and physiological stress. These protective mechanisms include avoidance motor reflexes, alterations in autonomic output and increased neuroendocrine response. Hence pain perception has cognitive and emotional components. Natural negative feedback mechanisms, such as central descending pain pathways, regulate the perception of pain.

Conversely, chronic pain is considered as a non-protective mechanism, and the bio-psycho-social model describes it as a specific disease (Phillips and Claw, 2013).

6.1.2 Current pain model

6.1.2.1 Nociceptors

Broadly, pain processing can be divided into four main processes: nociception, transmission, modulation and perception. Nociception is the process whereby a noxious stimulus is detected by a nociceptor which converts this into an electrical impulse. Nociceptors are mostly bare nerve endings which penetrate past the epidermal/dermal junction and are attached to fine fibres. Thin unmyelinated fibres (C fibres) are present in several structures, such as the joint (except in the cartilage), muscles, ligaments and viscera. There are several types of nociceptors which can be classified by the type of stimulus to which they respond: mechanical, thermal, chemical or polymodal (responds to multistimuli).

Until recently, it was thought that nociceptors were only found in the external region but not the internal region. However, recent studies have shown that internal nociceptors are present in the urogenital and gastrointestinal tract, although the density of these receptors is often much lower, which may explain, in part, why visceral pain is often less well localised than somatic pain.

6.1.2.2 Transmission

Transmission is the process whereby the signal of nociceptor activation is transmitted by sensory nerve fibres to the spinal cord from various parts of the body. There are three main types of nerve fibres: A- β , A- δ and C fibres. A- β fibres transmit tactile sensation, whereas A- δ and C fibres transmit pain. All these fibres have a lower threshold for stimulation than mechanoreceptors. Conduction by A- δ fibres (40 mph) is much faster than by C fibres (3 mph). Transmission can be inhibited by local anaesthetics and α -2 δ agonists, which affect calcium transport.

6.1.2.3 Modulation

All sensory information enters the spinal cord via the dorsal root. The dorsal horn of the spinal cord is a vital area for sensory processing and pain perception and modulation. It is divided into laminae I–VI. Sensory nerve fibres synapse via the superficial laminae. Numerous pain neurotransmitters are present in the area. Substance P, aspartate and glutamate are the main excitatory amino acids produced by the afferent neurons. They amplify the pain signals in ascending projection neurons and are the key molecules in pain transmission: this is described as ‘the wind-up phenomenon’.

Pain mechanisms are modulated by two main processes. First, segmental inhibition by a non-noxious stimulus transmitted by large afferent myelinated fibres subserving epicritical sensation inhibitory neurons (figure 5).

Second, 'descending inhibition' from several regions in the brain: peri-aqueductal grey, reticular formation and nucleus raphe magnus, sending inhibitory fibres down the spinal cord to modulate pain at the level of the dorsal horn. They can act either presynaptically on the primary afferent neurons or post-synaptically on second-order neurons. These endogenous inhibitory descending neurons release opioids, serotonin and norepinephrine (NE) to dampen the nociceptive response. Local anaesthetics, α -2 agonists, opioids, NSAIDs, tricyclic antidepressants, serotonin-selective reuptake inhibitors (SSRIs), serotonin NE reuptake inhibitors (SNRIs) and N-methyl-D-aspartate (NMDA) receptor antagonists can affect the balance between pain amplification and inhibition by their effect on pain modulation.

Figure 5 Pain modulation in the dorsal horn of the spinal cord.

The overall pain perception depends on the balance between excitatory and inhibitory neurotransmitters. Such physiological pain modulation is often applied clinically in many musculoskeletal diseases where nociceptors detecting pain are present in structures such as the synovium, joint capsule, bone, muscles and ligaments. When nociceptors are activated, pain signals are transmitted by peripheral nerve fibres to the spinal cord and the brain. These messages can be over-ridden by other signals produced by treatments such as massage, heat or cold packs, transcutaneous nerve stimulation, drugs or even acupuncture.

6.1.2.4 Perception

Perception is the response of the brain to nociceptive signals. Neuronal signals from the dorsal horn of the spinal cord transmit to the specialised areas of the somatosensory cortex via the thalamus. Initially, pain was thought of as a mere extension of the sense of touch. This is clearly too simplistic. Precisely how the brain

perceives pain remains unclear, but the advent of functional neuroimaging using technologies such as fMRI, has allowed greater insight into the perception of pain by the brain. During pain perception, aside from the somatosensory cortex, many areas of the brain become activated (table 1). One area that is strongly activated during pain stimulation is the parieto-insular cortex, which appears to be crucial for pain processing in the brain. Lesions damaging this region in the brain can reduce pain perception. Another important area is the caudal part of the anterior cingulate cortex, which has been implicated in the control of motivational behaviours. Activation of this area is linked to perception of the unpleasantness of pain, and is accompanied by activation in several subcortical sites, such as the amygdala, cerebellum and striatum. Other areas of the brain that are activated include the rostral anterior cingulate cortex, which has been implicated in pain inhibition.

Table 1 Regional cerebral blood flow after various stimuli

Brain region	Stimuli that increase blood flow	Painful or non-painful?
Contralateral primary somatosensory cortex (S1)	Mechanical	Painful and non-painful
Contralateral secondary somatosensory cortex (S2)	Mechanical	Painful and non-painful
Anterior cingulate cortex	Mechanical Catastrophising	Painful
Insula	Mechanical Aversive stimuli Depression	Painful
Thalamus	Mechanical	Painful

Overall, pain processing has huge inter-individual variability—a minimal stimulus in some subjects can cause them to register a large amount of pain, but conversely, a large stimulus in others can result in no pain being registered. Mogil has extensively reviewed this variability, which has been demonstrated both in rodents and humans (Mogil, 2009). Although the relative importance of genetic versus learning in this variability remains unclear, a large body of evidence suggests that genetic factors may have a significant contribution to pain perception. Moreover, pain perception is not ‘hard-wired’ but ‘plastic’. The term ‘neuroplasticity’ is often used to describe the changeability of the response of the nervous system to pain at peripheral and central locations.

6.1.3 Abnormal pain perception in fibromyalgia

Pain perception can malfunction owing to functional abnormality or pathology of the nervous system. Clifford Woolf called such pathological pain ‘maladaptive’. One of the key features of maladaptive pain is increased sensitivity or hyper-responsiveness. Clinically this is often manifested as ‘hyperalgesia’ and/or ‘allodynia’. Hyperalgesia is defined as ‘an increased response to a normally noxious stimulus’. Hyperalgesia can be normal

and transient. Allodynia is defined as painful response to normally non-noxious stimuli. Tender points in FMS are manifestations of allodynia: patients reporting pain when a sub noxious pressure is applied. Both hyperalgesia and allodynia result from similar mechanisms: 'peripheral' and central sensitisation'.

6.1.3.1 Peripheral sensitisation

Peripheral sensitisation is a reduction in threshold and an increase in responsiveness of the peripheral ends of nociceptors. When a noxious stimulus is applied to an area on the skin a small localised area of active tissue hyperalgesia develops owing to sensitisation of local nociceptors. This will spread out to involve a larger area of 'secondary hyperalgesia' over the next few hours. This leads to an increased response to painful stimuli known as primary hyperalgesia or peripheral sensitisation. In the case of inflammation this results from the release of inflammatory mediators by neutrophils, such as prostaglandin E2, which reduces nociceptor thresholds. NSAIDs act by inhibiting cyclo-oxygenase 2 and thereby reducing prostaglandin E2 production. Peripheral sensitisation contributes to the pain hypersensitivity found at the site of tissue damage and inflammation, as exemplified by that occurring in hypersensitivity after sunburn.

Recently, Caro and colleagues showed that the reduction in epidermal nerve fibre density is often (but not always) associated with significant neuropathic pain (hence the name small-fibre neuropathy (SFN)), and it can reasonably be expected to give rise to a clinically detectable loss of skin sensation (so-called negative sensory phenomena) rather than painful peripheral symptoms (positive sensory phenomena). However, SFN is associated with both, and it is thought that the painful peripheral symptoms of SFN are attributable to the disproportionate hyperexcitability of lesioned (but still functioning) primary small nerve fibres surrounded by a structurally normal but physiologically hyperexcitable group of secondary small nerve fibres that respond collaterally (Caro and Winter, 2014).

6.1.3.2 Central sensitisation

Central sensitisation refers to mechanisms that lead to an increase in the neuronal excitability in the central nervous system. Several mechanisms may lead to central sensitisation: action potential windup, receptor field expansion and hyperexcitable neuronal response. Action potential windup results from repeated stimulation of afferent nerve fibres in the dorsal root. This leads to a progressive increase in the number of action potentials generated, prolonging the duration of the discharge by interneurons even after the afferent fibre input has ceased. Receptor field expansion results from activation of neurotransmitter receptors, especially NMDA, leading to adjacent neurons in neighbouring areas becoming responsive to stimuli whether they are painful or not. Hyperexcitability of neuronal responses results from the release of substances that increase neuronal sensitivity. Many molecules have been implicated in the development of central sensitisation, including substance P, glutamate and aspartate. In general, these substances augment membrane excitability by increasing intracellular calcium concentration. For example, glutamate and aspartate activate the NMDA

receptor and resultant intraneuronal elevation of calcium, which stimulates nitric oxide synthase to produce nitric oxide. The latter is a gaseous molecule, which diffuses out from the neuron and stimulates the formation of cyclic guanosine monophosphate in neighbouring neurons, which can decrease the activity of γ -aminobutyric acid—an inhibitory neurotransmitter. Nitric oxide has been implicated in the development of hyperexcitability, resulting in hyperalgesia or allodynia (Phillips and Claw, 2013; Clauw, 2014).

Tender points, which were part of the 1990 ACR classification criteria for FMS, are a manifestation of allodynia. Recent research using more objective assessment has demonstrated a reduced pressure pain threshold over wide areas in patients with FMS not limited to the sites of tender points. It leads to the hypothesis that the pivotal pathophysiology in FMS is central sensitisation.

Furthermore, in patients with FMS, pain elicited from uninjured tissues around the site of pain, secondary hyperalgesia, was found to be increased in comparison with controls. When an electrical stimulus was applied to the skin of patients with FMS they had reduced pain thresholds and pain was noted both distally and proximally to the stimulator lasting for up to 20 min after the stimulation was stopped. Similarly, when hypertonic saline was injected into the anterior tibial muscle to induce pain, patients with FMS had a larger area of pain, which also lasted longer, than that felt by healthy age-matched controls. Pressure pain and the intramuscular summation pain threshold were significantly lower in patients with FMS.

In another study patients with FMS and age-matched healthy controls were given repeated tonic thermal stimuli over the skin stimulation at noxious and subnoxious level (Lautenbacher, 1997). While healthy controls had a significant increase in pain threshold, patients with FMS did not. This failure to down-modulate the pain threshold suggests central sensitisation and failure of the descending inhibitory pathways. An fMRI study comparing patients with FMS and healthy controls found reduced activity in the rostral anterior cingulate cortex, which is linked to the descending pain regulating system (Cook *et al*, 2004). There are two key descending pain regulatory pathways: one involves serotonin/epinephrine and the other, endogenous opioids. A positron emission tomography study showed that patients with FMS have reduced mu-opioid receptor occupancy potential compared with that of normal healthy controls, providing further support for the suggestion that there is abnormal central pain processing in FMS (Harris *et al*, 2007).

The results of these clinical studies are further supported by research using functional neuroimaging. Functional changes in the central nervous system have been investigated by several imaging techniques such as SPECT and fMRI scans. Using the latter, Gracely *et al* (2002)* have shown objectively that fMRI imaging matches the patient-reported pain in FMS. Furthermore, in comparison with normal age-matched healthy controls, patients with FMS have a lower pressure pain threshold. It also showed activation of different parts of the brain, including the thalamus. Acute pain increases thalamic blood flow while chronic pain states are associated with reduced thalamic blood flow. It has been postulated that disinhibition of the medial thalamus

leads to activation of the limbic system. The latter is a complex set of structures that lies underneath the thalamus, just under the cerebrum. It includes the hypothalamus, the hippocampus, the amygdala and several nearby areas. It is primarily involved in emotion and formation of memories. It has been suggested that the limbic system is associated with the descending inhibitory pathway. During acute pain, the limbic system is activated to repress pain signals in the spinal cord. In chronic pain decreased activity in the limbic system leads to hypersensitivity to pain. Mountz *et al* reported that on SPECT imaging, patients with FMS have decreased thalamic and caudate blood flow compared with healthy controls (Mountz *et al*, 1995).

Abnormal levels of neurotransmitters have been reported in patients with FMS. Increased levels of substance P and nerve growth factor in the cerebrospinal fluid have been reported in patients with FMS compared with controls. Substance P is released by afferent neurons in the dorsal horn and lowers the threshold of synaptic excitability, and sensitises second-order spinal neurons. Two studies in patients with FMS have found a threefold increase of substance P in the cerebrospinal fluid. Nerve growth factor is critical for the differentiation and survival of sensory neurons. It increases the production of substance P in afferent nerve fibres, reducing the pain threshold. The nerve growth factor level in the cerebrospinal fluid of patients is up to four times higher in patients with FMS than in controls. Conversely, the neurotransmitter serotonin, released by some inhibitory neurons, has been found to be present at lower than normal levels in patients with FMS.

Taken together there is substantial clinical and neuroimaging evidence to suggest that abnormal pain processing is important in the pathophysiology of FMS, but its specificity is still to be demonstrated.

6.2 Sleep disturbance

One of the most common symptoms of FMS is non-restorative sleep. Moldofsky *et al* first showed that the disruption of stage 4 non-rapid eye movement (non-REM) or deep sleep in normal healthy people by noise stimuli resulted in unrefreshing sleep, variable aching and fatigue (Moldofsky *et al*, 1975). These results have since been replicated by other studies. Sleep studies in patients with FMS have confirmed that poor sleep quality is associated with non-dreaming, non-REM sleep with interruption by alpha waves. Worse tenderness in the morning and cognitive impairment in FMS may be related to chronic sleep disturbance. Phasic alpha sleep patterns are associated with longer duration of pain symptoms, perception of poor sleep and morning pain.

In many patients with FMS improvement of sleep quality often significantly improves other symptoms.

6.3 Hypothalamic–pituitary–adrenal axis

Hypothalamic–pituitary–adrenal (HPA) axis dysfunction has been demonstrated as part of the pathophysiology of patients with FMS. The HPA axis is a critical orchestrator of the body's response to stress. It influences various processes, such as digestion, the immune system, mood and energy. Normally corticotrophin-releasing

hormone produced by the hypothalamus stimulates the anterior pituitary gland to release adrenocorticotrophic hormone (ACTH). ACTH stimulates the production of glucocorticoids by the adrenal cortex. The release of these hormones is under circadian control with rapid increase in cortisol levels shortly after wakening, reaching a peak within 30–45 min. It then diminishes over the day, until rising again in late afternoon. Cortisol levels then fall in late evening, reaching a trough during the middle of the night. Stress-induced release of corticotrophin-releasing hormone from the hypothalamus is influenced by blood levels of cortisol and by the sleep/wake cycle. Increased production of cortisol mediates responses to stress, allowing the body to attempt counter measures. However, chronic excessive production of cortisol can be damaging. Atrophy of the hippocampus in humans and animals exposed to severe stress is believed to be mediated by prolonged exposure to high concentrations of cortisol.

The HPA axis is closely linked with the limbic system, especially the thalamus, amygdala and hippocampus which facilitate activation of the HPA axis. Sensory information arriving at the lateral aspect of the amygdala is processed and conveyed to the central nucleus, which projects to several parts of the brain involved in responses to fear. At the hypothalamus fear-signalling impulses activate both the sympathetic nervous system and the modulating systems of the HPA axis. Deficiencies of the hippocampus may reduce the memory resources available to help a body formulate appropriate reactions to stress. The HPA axis is also linked to the autonomic nervous system, which is involved in modulating sleep, mood, pain and cardiovascular activities (including microcirculation of muscles). Many symptoms of FMS may be explained by sympathetic nerve system overactivity, although more detailed mechanistic studies are needed to confirm a causative relationship.

In patients with FMS, a reduced HPA axis response to stress has been demonstrated. The main HPA abnormalities in FMS are:

- low free cortisol levels in 24 h urine samples;
- loss of the normal circadian rhythm with increased evening cortisol level;
- insulin-induced hypoglycaemia associated with an overproduction of pituitary ACTH;
- low levels of growth hormone;
- reduced adrenal release of glucocorticoids in response to ACTH stimulation.

Patients with FMS often report previous stressful or traumatic events. Some patients consider that such events might have precipitated their illness. A reduced HPA axis response to stress can contribute to the development of FMS or worsening of symptoms. Furthermore, patients with FMS often have worse pain and tenderness in the morning and significant morning stiffness. Often this improves after nights where they have had more

restful sleep. Although a causal relationship has not been established, HPA axis dysfunction may contribute to the development of these symptoms. Alternatively, as a dysfunctional HPA axis has been implicated in the pathophysiology of many disorders, including anxiety, depression, post-traumatic stress disorder, CFS, sleep disturbances and IBS, the HPA abnormalities seen in FMS may reflect other comorbidities.

6.4 Genetics of fibromyalgia

Several polymorphisms have been associated with an increased risk of fibromyalgia. One of the most frequently reported polymorphism is the mutation of catechol-O-methyl transferase, an enzyme-degrading catecholamine. The association of the catechol-O-methyl transferase genotype with psychological distress may identify FMS subgroups.

6.5 Summary of pathophysiology in FMS

Although the pathogenesis of FMS remains unclear, the known abnormalities support the hypothesis that FMS is related to specific pain mechanism abnormalities. Somatosensory abnormalities, cerebrospinal fluid and functional neuroimaging studies all suggest that abnormal pain processing is the central pathophysiological process in FMS.

6.6 Pathophysiology in CFS

The aetiology and pathogenesis of CFS remain unknown, although abnormalities of the nervous, immune systems and HPA axis have been reported. Chronic fatigue is not unique to CFS, and is also present in many chronic diseases. In both instances fatigue limits physical and mental activities.

7 Management

As FMS is a complex syndrome associated with a wide range of symptoms, treatment should be tailored to the individual, dealing with their particular needs and targeting their most distressing symptoms. The best strategy is to use a multidisciplinary approach to treatment, using both pharmacological and non-pharmacological interventions as required (Carville *et al*, 2008; Hauser *et al*, 2009). It is unlikely that a single treatment will target all of the symptoms involved (Clauw, 2014). The different subgroups of patients with FMS are likely to respond differently to treatment strategies, highlighting the fact that patients should be managed according to their individual needs, rather than following a generalised approach. A EULAR task force developed management recommendations for FMS based on a systematic review, which are summarised in table 2.

Table 2 EULAR recommendations for the management of fibromyalgia

Recommendation	Level of evidence	Strength
General		
Full understanding of fibromyalgia requires comprehensive assessment of pain, function and psychosocial context. Fibromyalgia should be recognised as a complex and heterogeneous condition where there is abnormal pain processing and other secondary features	IV	D
Optimal treatment requires a multidisciplinary approach with a combination of non-pharmacological and pharmacological treatment modalities tailored according to pain intensity, function, associated features such as depression, fatigue and sleep disturbance, in discussion with the patient	IV	D
Non-pharmacological management		
Heated pool treatment with or without exercise is effective in fibromyalgia	IIa	B
Individually tailored exercise programmes including aerobic exercise and strength training can be beneficial to some patients with fibromyalgia	IIb	C
Cognitive behavioural therapy may be of benefit to some patients with fibromyalgia	IV	D
Other treatments such as relaxation, rehabilitation, physiotherapy and psychological support may be used depending on the needs of the individual patient	IIb	C
Pharmacological management		
Tramadol is recommended for the management of pain in fibromyalgia		
Simple analgesics such as paracetamol and other weak opioids can also be considered in the treatment of fibromyalgia. Glucocorticoids and strong opioids are not recommended	Ib IV	A D
Antidepressants: amitriptyline, fluoxetine, duloxetine, milnacipran, moclobemide and pirlindole, reduce pain and often improve function, therefore they are recommended for the treatment of fibromyalgia	Ib	A
Tropisetron, pramipexole and pregabalin reduce pain and are recommended for the treatment of fibromyalgia	Ib	A

Three drugs are licensed for treatment of FMS in the USA: pregabalin (Pfizer), duloxetine (Eli Lilly) and milnacipran (Forrest). However, there are other treatments which have evidence to support their efficacy in FMS.

7.1 Non-pharmacological management

Owing to the lack of a 'gold standard' treatment for FMS, a wide range of non-pharmacological approaches have been tested with varying success and more research will be required to further define the role of some of these treatments in FMS. Non-pharmacological treatments which have been tested in FMS include: exercise, cognitive behavioural therapy (CBT), homoeopathy, physiotherapy, acupuncture, magnetism, dietary alterations and laser therapy. These interventions are generally safe and therefore long-term use is not

detrimental. The potential benefits of non-pharmacological interventions should not be overlooked by practitioners when treating patients with FMS. The list of EULAR-recommended non-pharmacological interventions is given in box 2. They can be implemented in isolation or combined with other non-pharmacological or pharmacological agents, depending on the patients' needs.

Box 2 Non-pharmacological treatment for fibromyalgia syndrome

- Patient education
- Graded exercise
- Heated water therapy with or without exercise
- Cognitive behavioural therapy
- Relaxation
- Rehabilitation
- Physiotherapy
- Psychological support
- Complementary and alternative medicine—for example, acupuncture, dietotherapy, etc

7.1.1 Patient education

As FMS is a chronic condition without a permanent remedy, patient education is an important aspect of management as patients have to learn to manage their pain even if they also receive other treatment. They should also understand that it is unlikely that the symptoms will ever completely resolve. This may help to improve their long-term prognosis by providing more realistic health beliefs.

7.1.2 Graded exercise

Most experts concur that aerobic exercise and strength training are beneficial for patients with FMS and this is supported by systematic reviews (Hauser *et al*, 2010). Patients with FMS can exercise like healthy people, but at levels tailored to each individual. When performing strength training they can achieve the same strength gains, which may in turn lead to functional improvements and better quality of life. It should be noted that exercise may not improve pain, indeed it may become worse at first. However, there is good evidence that it can lead to improvements in physical function, tender point count, aerobic performance and global well-being. Adherence to exercise programmes may be a limiting factor, therefore education on the benefits and risks of exercise should be given. Patients should be advised that exercise is not harmful in FMS and does not cause any muscle damage or worsening of FMS. Long-term exercise is without risks and has other health gains, although programmes should be monitored and graded according to the functional ability of the patient. Education can improve adherence to exercise programmes. Patients should be advised before and during their exercise programme so that they do not have unrealistic treatment goals or worries.

Some patients find that heated pool-based exercise is particularly beneficial; hydrotherapy can be effective for pain relief even without exercise. Buoyancy reduces pressure load from the muscles and the heated water

provides relaxation. Pain relief may only be temporary, but treatment can be maintained long term without any safety concerns. Treatment improves pain, function and reduces tender point count, although availability of a hydrotherapy pool and cost are limiting factors.

7.1.3 Cognitive behavioural therapy

CBT, often including patient education, has been shown to improve pain and function in FMS either as sole treatment or in combination with exercise. It may be particularly beneficial to provide CBT early after diagnosis to help patients understand FMS and learn how to develop more effective coping strategies. Furthermore, encouraging patients to be actively involved in self-management is desirable (Bernardy *et al*, 2013).

7.1.4 Other non-pharmacological treatments

A range of dietary interventions have been studied in FMS, but evidence of their efficacy is limited. Complementary treatments, including homoeopathic remedies and acupuncture, have also been reported to have benefits for pain, tenderness, quality of life and well-being of patients with FMS. There have also been negative studies for acupuncture but it may benefit some patients. A number of miscellaneous treatments have also been used in FMS, including treatment with lasers, magnets, ultrasound and music vibration. The paucity of evidence does not allow firm conclusions or recommendations to be made about these treatments (Cassisi *et al*, 2013).

7.2 Pharmacological treatments

Medication should be used in combination with a non-pharmacological intervention in the management of FMS. As with non-pharmacological interventions a number of pharmaceutical agents have been tested and should be considered for patients with FMS (box 3) (Clauw, 2014).

Box 3 Pharmacological treatment for fibromyalgia syndrome

- Simple analgesics
- Tramadol
- Tricyclic antidepressants
- Serotonin–norepinephrine reuptake inhibitors: milnacipran, duloxetine, venlafaxine
- $\alpha 2$ Agonists—for example, gabapentin, pregabalin

7.2.1 Analgesics

Tramadol is a useful, moderately potent, opioid analgesic that improves pain but not function in FMS. It acts centrally and inhibits NE and serotonin reuptake while also being an agonist for the mu opioid receptor. Most commonly reported adverse events include nausea, somnolence, constipation and dizziness. However, it should be prescribed with caution as typical opiate withdrawal can be experienced when it is stopped—so

careful down-titration must be observed. Dependence and abuse are also potential problems to bear in mind when prescribing. Other systemic analgesics have been used in short-term studies, including lidocaine, ketamine and morphine. While ketamine and lidocaine have received some support for short-term pain relief (after injection), there is doubt about their efficacy for treating a chronic condition such as FMS. Topical analgesics (including xylocaine and capsaicin) are not of benefit in this condition.

NSAIDs may be useful for short-term pain relief when used in addition to other treatments (e.g., stretching exercises). However, they should not be considered as an option for long-term management owing to their gastrointestinal effects. Further to this, most studies of NSAIDs have produced negative results in FMS. In the recent merged German and Israeli guidelines, NSAIDs, strong opioids and benzodiazepines are not recommended (Ablin *et al*, 2013a; Ablin *et al*, 2013b).

7.2.2 Antidepressant drugs

Antidepressant drugs should be considered for patients with FMS (Häuser *et al*, 2014). Tricyclic antidepressants (TCAs), SSRIs, dual reuptake inhibitors, monoamine oxidase inhibitors and serotonin antagonists have all been reported to have benefits. TCAs, such as amitriptyline, are the most widely used in FMS. They inhibit serotonin (5HT₃) and NE re-uptake, but also affect glutaminergic neurotransmission by acting on histamine, acetylcholine and NMDA channels. They can improve sleep, fatigue and pain in FMS (Nishishinya *et al*, 2008). The effect is independent of the drugs' antidepressant action as the doses prescribed are much lower than those for depression. Indeed, in clinical trials, the best result for amitriptyline was for a 25 mg dose rather than 50 mg. Despite the positive results, tolerance is poor, mainly due to the anticholinergic side effects, including dry mouth, digestive and neuropsychiatric disturbances.

SSRIs are better tolerated than TCAs as they have fewer anticholinergic side effects. However, randomised control trials of SSRIs in FMS produced mixed results, requiring higher doses for analgesic effect than for antidepressant effects. Fluoxetine has had some positive results, especially in association with amitriptyline (Don Goldenberg *et al*, 1996).

Dual reuptake inhibitors, SNRIs, seem to have similar efficacy to TCAs without the anticholinergic effects. Their tolerance is good (headaches and nausea are the most commonly reported adverse events) and studies for milnacipran, duloxetine and venlafaxine have all reported positive effects on pain, function, pain threshold, fatigue and quality of life (although the study of venlafaxine was open-label and non-randomised). Duloxetine and milnacipran have recently been licensed for the treatment of FMS by the Food and Drug Administration (FDA) in the USA.

Duloxetine is the first SNRI to be approved by the FDA for the treatment of FMS. In clinical trials, duloxetine 60 mg/day reduced pain and improved function. The recommended starting dose is duloxetine 30 mg once a day

for 1 week; the dose may be increased to 60 mg/day. The most common side effect of duloxetine is nausea. Other common side effects include dry mouth, constipation, decreased appetite, somnolence, increased sweating and agitation. It is contraindicated in patients taking monoamine oxidase inhibitors or thioridazine and patients who have uncontrolled narrow-angle glaucoma.

Milnacipran is the second SNRI approved by the FDA for the treatment of FMS. Like duloxetine, dose titration is recommended. The normal starting dose is 25 mg/day for 2 days. Increasing to 25 mg twice a day for 4 days, followed by the normal maintenance dose of 50 mg twice a day. Similarly to duloxetine, in clinical trials milnacipran reduced pain and improved function. The most frequent side effect adverse is nausea. Noradrenergic side effects such as dry mouth, hyperhidrosis, headache, hot flush and constipation are also common. Increases in blood pressure and heart rate are uncommon but monitoring is recommended. As for duloxetine, it is contraindicated in patients taking monoamine oxidase inhibitors.

Tropisetron and ondansetron are 5HT₃ receptor antagonists which have shown pain and tender point count improvements in patients with FMS but only in short-term studies (5–10 days). A recent study with dolasetron has demonstrated significant effect within a 3-month treatment (Vergne Salle *et al*, 2011).

Although the effects of these drugs for FMS are independent of their antidepressant actions, for those patients in whom depression is the predominant symptom, this should be the first given targeted antidepressant therapy.

A recent meta-analysis reported that TCA, amitriptyline, and the SNRIs, duloxetine and milnacipran, are first-line options for the treatment of patients with FMS, but only a small number of patients have substantial symptom relief with no or minor adverse effects. Moreover, a considerable number of patients drop out of treatment because of intolerable adverse effects or have only a small relief of symptoms, which does not outweigh the adverse effects (Häuser *et al*, 2012).

7.2.3 Other pharmacological interventions

Pregabalin and gabapentin are agonists of the $\alpha 2\delta$ subunit of the voltage-dependent calcium channel in neurons. They reduce calcium influx into the nerve terminals and decrease the release of neurotransmitters such as glutamate, NE and substance P. They were developed as antiepileptic agents initially but recent studies have shown efficacy in FMS. A large recent controlled study of pregabalin in patients with FMS reported good effects for sleep, pain and fatigue and good tolerability, with most adverse events being dizziness or somnolence, mild to moderate in severity. Pregabalin was the first drug which received approval from the FDA for treatment of FMS in the USA. In clinical trials, pregabalin 300 mg/day and 450 mg/day reduced pain and improved sleep quality. The recommended dose is 300–450 mg/day. Doses should begin at 75 mg twice a day and increase to 150 mg twice a day after 1 week. For patients who do not receive sufficient benefit the dose

may be further increased to 225 mg twice a day. Common side effects include dizziness, drowsiness, dry mouth, oedema, weight gain, constipation and increased appetite (Häuser *et al*, 2012).

Gabapentin has also been studied in FMS and produced good outcomes in a number of symptoms, including pain, function and quality of life. These results suggest that the α_2 calcium channel is a good therapeutic target in FMS.

Pramipexole is a dopamine agonist that was developed for the treatment of Parkinson's disease. However, it affects the mesolimbic system (particularly in sleep control), suggesting it might be a useful treatment for FMS. In a randomised control trial, it led to improvements in pain, fatigue, function and global well-being with good tolerance (Holman and Myers, 2005). However, this is based on one study in which patients were allowed to continue with current drug treatment if at a stable dose. Large randomised control trials are needed to confirm the benefits and risks of pramipexole for the treatment of FMS.

Hypnotics, including zolpidem, act on benzodiazepine receptors. In FMS they are effective for sleep and fatigue, but not pain, so should only be used in combination with another approach. Sodium oxybate (a commercial form of gamma hydroxybutyrate, Jazz Pharmaceutical) is known to increase slow-wave sleep and growth hormone levels (both impaired in patients with FMS). It has been shown to improve pain as well as fatigue and sleep in FMS. There is the potential for abuse with this drug, however, and it has been associated with date rape, so its use in FMS should be considered with caution.

Tizanidine, an α_2 adrenergic central agonist, probably acts by reducing levels of substance P in the central nervous system. It has been reported to reduce pain and improve sleep and quality of life in FMS; however, the study was not controlled or blinded. Adverse events can include tiredness, somnolence, dizziness and dry mouth. It should be used with caution in women receiving oral contraceptives, which can reduce its clearance.

Growth hormone has been studied in FMS owing to research showing reduced levels in patients with FMS. Although results were positive for quality of life and tender points, its usefulness is limited by potential side effects and high cost. There has been a suggestion that patients with FMS benefit from thyroid hormone therapy and that perhaps patients (or a subgroup of them) have a subclinical deficiency in this hormone. Three small studies by Lowe *et al* suggest that tri-iodothyronine is beneficial for pain and function after up to 8 months' treatment in euthyroid female patients with FMS. Each of these studies is small and the long-term toxicity of thyroid hormone remains a significant concern (Lowe *et al*, 1997).

7.3 Summary of management

Management of FMS is likely to require a multidisciplinary approach with a combination of pharmacological and non-pharmacological treatments. The goal of treatment is to reduce symptoms to a more tolerable level

as remission is rare. More research into FMS pathogenesis and treatment will hopefully lead to more promising medical development in this area.

Finally, pregabalin, duloxetine, milnacipran and amitriptyline are the current first-line prescribed agents but have mostly had a modest effect. With only a minority of patients expected to experience substantial benefit, most will discontinue treatment because of either a lack of efficacy or tolerability problems (Häuser *et al*, 2014).

7.4 Management of CFS

In the UK, the National Institute of Health and Care Excellence guidance on the management of CFS advise patient education, balanced diet, graded exercise and CBT. Pharmacological treatment such as antidepressant drugs, steroids and thyroxine in euthyroid patients are not recommended as evidence for their overall benefit is equivocal. Patients with CFS should be referred to a specialist within 6 months of presentation for those with mild symptoms, within 3–4 months for those with moderate symptoms and immediately for those with severe symptoms.

7.5 Disease-specific measures

Disease-specific measures are designed to assess specific diagnostic groups or patient populations, often with the aim of measuring responsiveness to treatment or 'clinically important' changes. One obvious disadvantage of some disease-specific measures is that they do not allow comparative judgements between the outcomes of different treatments in patients with different health problems. For example, in resource allocation studies the use of disease-specific measures may be combined with generic measures. However, there are some broad disease-specific measures for FMS, such as the FIQ or the revised FIQ, and the Health Assessment Questionnaire, which include general aspects of functional status together with specific references to states or changes of particular concern to the target population.

Salaffi *et al* validated a Fibromyalgia Assessment Status Index, which is a short and easy to complete self-administered index combining a set of questions relating to non-articular pain (Self-Assessment Pain Scale range 0–10), fatigue (range 0–10) and quality of sleep (range 0–10) that provides a single composite measure of disease activity ranging from 0 to 10. The final score is calculated by adding the three sub scores and dividing the result by three. All three measures are printed on one side of one page for rapid review, and scored by a health professional without the need for a ruler, calculator, computer or website. These disease-specific measures therefore considerably overlap generic measures (Salaffi *et al*, 2009).

SUMMARY POINTS

- General widespread pain is common and includes conditions such as multiple bursitis–tendonitis syndrome, fibromyalgia syndrome (FMS) and chronic fatigue syndrome (CFS).
- FMS is the commonest cause of generalised widespread pain and is characterised by reduced pain thresholds (hyperalgesia) and pain with normally innocuous stimuli (allodynia). Diffuse pain is often accompanied by a wide range of symptoms, including fatigue, sleep disturbance, functional impairment, cognitive dysfunction, variable bowel habits, depression, stiffness and more.
- Fatigue is the dominant clinical feature in CFS, but the clinical features of CFS and FMS overlap significantly.
- There is no assay or pathological test for FMS or CFS; diagnosis is based on symptoms and exclusion of other illnesses. For FMS, the American College of Rheumatology (ACR) 1990 classification criteria are commonly used as a diagnostic tool. Recently, the ACR published survey base diagnostic criteria for FMS which include the presence of widespread pain for at least 3 months. However, tender point count has been replaced by a symptom checklist which includes the Widespread Pain Index and Symptom Severity Scale.
- There are many sets of diagnostic criteria for CFS. In general, they include the presence of fatigue that is chronic and/or recurrent for more than 6 months, resulting in substantial reduction in activity, worsens on exertion and is unexplained by other conditions. Some of these criteria include other symptoms such as sore throat, muscle pain, cognitive dysfunction, tender lymph nodes, chemical hypersensitivity, headache and unrefreshing sleep. Exclusion criteria include psychotic, melancholic or bipolar depression, psychotic disorders, dementia and anorexia or bulimia nervosa.
- FMS is common, affecting 2% of the population with a female to male ratio of 7:1. Impaired physical function and reduced quality of life are common and comparable with diseases such as rheumatoid arthritis. Medical costs are high, up to 10 years before diagnosis. The societal cost of FMS due to reduced productivity is high. Constructive diagnosis can reduce healthcare costs.
- FMS is heterogeneous. Although depression is common, it does not always occur and mood should be assessed in all patients. Patients with moderate to severe depression, especially those with suicidal thoughts, should be referred to a psychiatrist for further assessment and management.
- Physiological pain is important in protecting the organism from harm while maladaptive (pathological) pain injury is caused by functional abnormality of the nervous system. FMS is characterised by maladaptive pain which has been demonstrated by functional MRI scan and detailed somatosensory testing.
- Sleep disturbance is common in patients with FMS. Polysomnography has confirmed reduced deep quality sleep and increased wakefulness. In healthy volunteers, selective deprivation of non-rapid eye movement sleep can induce symptoms and hyperalgesic tender sites of FMS.
- Non-pharmacological interventions for FMS, such as graded exercise and warm water bath, are important. Patients should be warned that pain may worsen transiently when starting exercise but should persevere. Other options include cognitive behavioural therapy, relaxation, rehabilitation, physiotherapy and psychological support, which may be used in some patients.
- Pharmacological treatments for FMS, as described in the EULAR recommendations, may be useful adjuncts to non-pharmacological treatments and should be considered. Choice of drug will depend on clinical manifestations.

IN-DEPTH DISCUSSION I

Do we need new classification criteria for fibromyalgia syndrome?

The American College of Rheumatology (ACR) classification criteria for Fibromyalgia Syndrome in 1990 were used as diagnostic criteria for 20 years, although there were developed as classification criteria. These ACR1990 FM criteria had a major beneficial impact on research and clinical practice. They are widely used in research as well clinical practice to diagnose the condition. It stipulates an individual must have both chronic widespread pain involving all four quadrants of the body as well as the axial skeleton, and the presence of 11 of 18 tender points on examination. Since clinical researchers are now using the classification criteria extensively, it allows comparison and pooling of results from different studies. Furthermore, when applied in routine clinical practice, the diagnosis of FMS using the criteria reduces healthcare utilization.

Recently, the American College of Rheumatology published survey base criteria for FMS, a further modified version was published in 2011. The preliminary ACR 2010 criteria for the diagnosis of FMS do not require physical examination but the requirement for the presence of widespread pain for at least three months and that the patient does not have a disorder that would otherwise explain the pain are retained. However, tender point count has been replaced by a symptom checklist which includes Widespread Pain Index (WPI) and Symptom Severity Scale (SSS).

In the WPI, patients are asked to indicate the regions (maximum 19 regions) of the body in which pain has been experienced during the past week. Each positive region is given a score of 1 (WPI ranges 0 to 19).

SSS is the sum of the severity of the 3 symptoms (fatigue, waking unrefreshed, cognitive symptoms) plus the extent (severity) of somatic symptoms in general. Each of the 3 symptoms: severity of fatigue, waking unrefreshed and cognitive symptom, is scored between 0-3 (0 = no problem, 1 = slight or mild problems, generally mild or intermittent, 2 = moderate, considerable problems, often present and/or at a moderate level, 3 = severe: pervasive, continuous, life-disturbing problems over the last week). The extent of somatic symptoms is also scored between 0-3 (0 = no symptoms, 1 = few symptoms, 2 = a moderate number of symptoms and 3 = a great deal of symptoms). Permissible somatic symptoms include: muscle pain, irritable bowel syndrome, fatigue/tiredness, thinking or remembering problem, muscle weakness, headache, pain/cramps in the abdomen, numbness/tingling, dizziness, insomnia, depression, constipation, pain in the upper abdomen, nausea, nervousness, chest pain, blurred vision, fever, diarrhoea, dry mouth, itching, wheezing, Raynaud's phenomenon, hives/welts, ringing in ears, vomiting, heartburn, oral ulcers, loss of/change in taste, seizures, dry eyes, shortness of breath, loss of appetite, rash, sun sensitivity, hearing difficulties, easy bruising, hair loss, frequent urination, painful urination, and bladder spasms. The final SSS is between 0 and 12.

A patient satisfies the criteria for FMS if the following conditions are met: WPI >7 and SS scale score >5 or WPI 3–6 and SS scale score >9.

Removing the reliance on tender point count is the major advantage of the survey base criteria for FMS. In addition the SSS includes characteristic features of FMS and may be used to monitor disease activity. These criteria are not intended to replace the ACR 1990 classification criteria, but to represent an alternative method of diagnosis.

A global survey by the independent polling organization Harris Interactive of 800 patients with FMS and 1,622 physicians from eight countries (the UK, France, Germany, Italy, Spain, the Netherlands, Mexico and S. Korea) found that average time taken to have FMS diagnosed was 2 years while the number of physicians consulted was 3. Yet delay in the diagnosis has been shown to be a factor that is associated with a poor outcome by a study in Spain and also higher healthcare utilization. The global survey also found between 40-50% of primary care physicians and 50-60% of specialists felt FMS is difficult to diagnose.

A study has suggested FMS patients can be divided into three different sub-groups based on their symptoms, coping strategy and tenderness level. These three sub-groups have been discussed in the main review.

Lastly, our understanding of pathophysiology of pain processing has been greatly advanced by the availability of new research techniques. Quantitative sensory testing and functional MRI scan have shown objectively that patients with FMS have reduced pressure pain threshold, and PET has shown that mu-opioid receptor binding is decreased in multiple pain processing regions in the brains. Ideally, any new diagnostic criteria should correspond to the pathophysiology of FMS.

In conclusion, whilst the American College of Rheumatology 1990 classification criteria of fibromyalgia have made a significant contribution to research and clinical practice, the new 2010 modified Criteria will improve diagnosis but also severity assessment for graded management.

IN-DEPTH DISCUSSION II

Is reduced sleep quality a purely secondary phenomenon in fibromyalgia?

Poor quality, unrefreshing sleep is a prominent feature of fibromyalgia syndrome (FMS). 70-90%^{1,2} of patients diagnosed with FMS complain of some type of sleep disturbance including difficulty getting to sleep, frequent wakening, and light sleep. Daytime sleepiness and morning fatigue, feeling the need to sleep shortly after waking, may occur in 75–80% of patients³. Morning fatigue is a good indicator of unrestorative sleep, where the quantity of sleep may be normal but the quality is reduced.

Many people have felt that this effect on sleep is a secondary phenomenon, and it is clear that pain will negatively effect sleep. The association between the two has been well described not only in populations with chronic rheumatic conditions⁴ but in the general population. A large epidemiological study in Germany found that those with chronic widespread pain were more likely to describe poor sleep than those without⁵. However, as the sleep cycle is better understood it is becoming clear that its role may be primary as well.

The sleep cycle is split into NREM, non-rapid eye movement, and REM, rapid eye movement. Most sleep is NREM in nature. There are 4 types of NREM sleep, N1 at the interface between wakefulness and sleep through to N4, slow wave sleep or delta sleep when it is at its deepest. REM sleep has tonic and phasic components. The phasic component is characterized by rapid eye movements, muscle twitches, and respiratory variability and is sympathetically driven. Tonic REM is a parasympathetically driven state with no eye movements.

It is normal to have predominantly delta waves in N2, 3 and 4 with alpha waves occurring in less than 40% of normal NREM sleep⁶. In studies of sleep in patients with FMS frequent alpha wave intrusions into delta wave sleep, so called alpha delta sleep, have been recorded in stages N2, 3, and 4⁶. Increased amounts of differing alpha EEG sleep types have also been recorded. Phasic alpha sleep in 50% of patients compared to 7 % of normal and tonic in 20% of patients compared to 9%⁷. Sleep with low levels of alpha EEG activity occurred in only 30% of patients compared to 84% of normal. Of these those with the phasic pattern of alpha EEG sleep had an increased incidence of pain, increased tenderness on wakening, poor sleep efficiency and less slow wave sleep than the other groups. FM patients have a higher cyclic alternating pathway (CAP) rate than normal subjects⁷. The CAP rate describes instability of the level of vigilance that manifests the brain's fatigue in preserving and regulating the macrostructure of sleep. Patients with FMS had twice as many arousals per hour of sleep than normal and spent a greater proportion of time in stage 1 of NREM sleep. The CAP rate (total CAP time/non-REM sleep time) was significantly increased in FM patients compared to controls (68 +/- 6% vs. 45 +/- 11%; $p < 0.001$) and this increase correlates with the severity of clinical symptoms in FM patients (tender points index; $p < 0.01$) and with less sleep efficiency (time in bed/time asleep).

These studies suggest that different patterns of sleep may occur in patients who already have symptoms of FMS but a causal link between disturbed sleep and pain has also been demonstrated⁵. Moldofsky took 6 young men with no history of chronic pain and used auditory stimulation to disturb their NREM sleep⁵. Using polysomnography they were monitored whilst sleeping and as they entered stage 4 sleep the auditory

stimulation was used to induce alpha waves but not to wake them. This took place over 3 consecutive nights. During this period overnight increases in dolorimeter scores were recorded and increased musculoskeletal symptoms, and mood disturbance comparable to patients those described by patients with FMS were reported. After a period of “recovery”, undisturbed sleep these symptoms resolved. This evidence which suggests a primary role for NREM sleep disturbance is supported by further studies^{8,9}.

Furthermore, animal studies have looked at the physiological effect of sleep and there is growing evidence of a direct effect on pain control mechanisms. Rat studies have shown that neurons in the pontomedullary raphe magnus (RM) are important in the descending modulation of nociceptive transmission. In unanaesthetised rats thermal stimulation can produce either suppression or facilitation of nociceptive dorsal horn cells and nociceptive reflexes depending on the state of sleep or wakefulness¹⁰. RM OFF cells discharge continuously during slow wave sleep but only intermittently during waking. When discharging during slow wave sleep the effect resembles OFF cell discharge after administration of analgesic doses of morphine. This is hypothesized to inhibit nociceptive transmission within the spinal dorsal horn. In human studies increased threshold of nociceptive flexion reflexes have been observed during sleep, particularly REM sleep¹¹. The nociceptive flexion reflex is controlled by multiple systems including endogenous opioids which are increased during sleep and it has been hypothesised that this may have an inhibitory effect which would be lost if sleep is disturbed. Further studies of sleep/pain physiology are required to piece together the effects that each has on the other.

The mounting evidence supporting the role of sleep in FMS has led investigators to examine whether therapies that manipulate sleep can be used to treat FMS. Previously hypnotics have been found to improve sleep quantity but they have not had a significant effect on somatic symptoms including pain¹². They should only be used in conjunction with other treatments for FMS. Recently encouraging research studying sodium oxybate (SXB) has been reported¹³⁻¹⁵. SXB increases slow wave sleep and reduces nocturnal waking. It also modulates activity of noradrenergic, serotonergic, dopaminergic, cholinergic, and glutamatergic neurons and promotes growth hormone secretion and the production of some neurosteroids. A UK based study has shown that treatment with 4.5g or 6g nightly for 14 weeks significantly improves pain compared to placebo¹⁴. A 30% reduction in pain from baseline was reported in 54.2% treated with SXB 4.5 g and 58.5% treated with SXB 6 g compared with 35.2% for placebo ($P < 0.001$ for both comparisons). This was maintained for 50% and 80% improvements in the 6g group. There were also significant improvements in fatigue, early morning fatigue, and functioning in the 6g group versus placebo. However, sodium oxybate is the sodium salt of c-hydroxybutyrate (GHB), an endogenous metabolite of c-aminobutyric acid (GABA) with central nervous system–depressant properties which is also known as a “date-rape” drug and is potentially open to abuse. In addition, tolerability may be an issue with an incidence of at least twice that of placebo for headache, nausea, dizziness, vomiting, diarrhoea, anxiety, and sinusitis. The 6 g dose was generally associated with a greater incidence of AEs than the 4.5 g dose. However, this study and others do indicate that by exploring treatments that improve the

quality of sleep we may be able to make a leap forward in managing patients with FMS and at the same time gain a better understanding of the pathogenesis of FMS.

Osteoporosis : Pathogenesis and Clinical features

Roland Chapurlat, Marine Gaudé, Christian Roux

A previous version was coauthored by Karine Briot, Christian Roux, Cyrus Cooper

LEARNING OBJECTIVES

- Describe and explain the physiology of bone (bone formation, bone resorption) and bone modeling and remodeling
- Outline the epidemiology of vertebral, hip and non- vertebral non-hip fractures
- Describe and explain the consequences of osteoporotic fractures: mortality, morbidity and risk for subsequent fractures
- Diagnose vertebral fractures
- Identify the role of bone density and T-scores for fracture risk assessment.
- State the role of FRAX calculation
- Perform adequate differential diagnosis for secondary osteoporosis
- Assess the risk of fracture in patients treated with glucocorticoids
- Recognise increased risk of osteoporosis and fractures in patients with inflammatory joint disorders.

This course does not address the treatment of osteoporosis

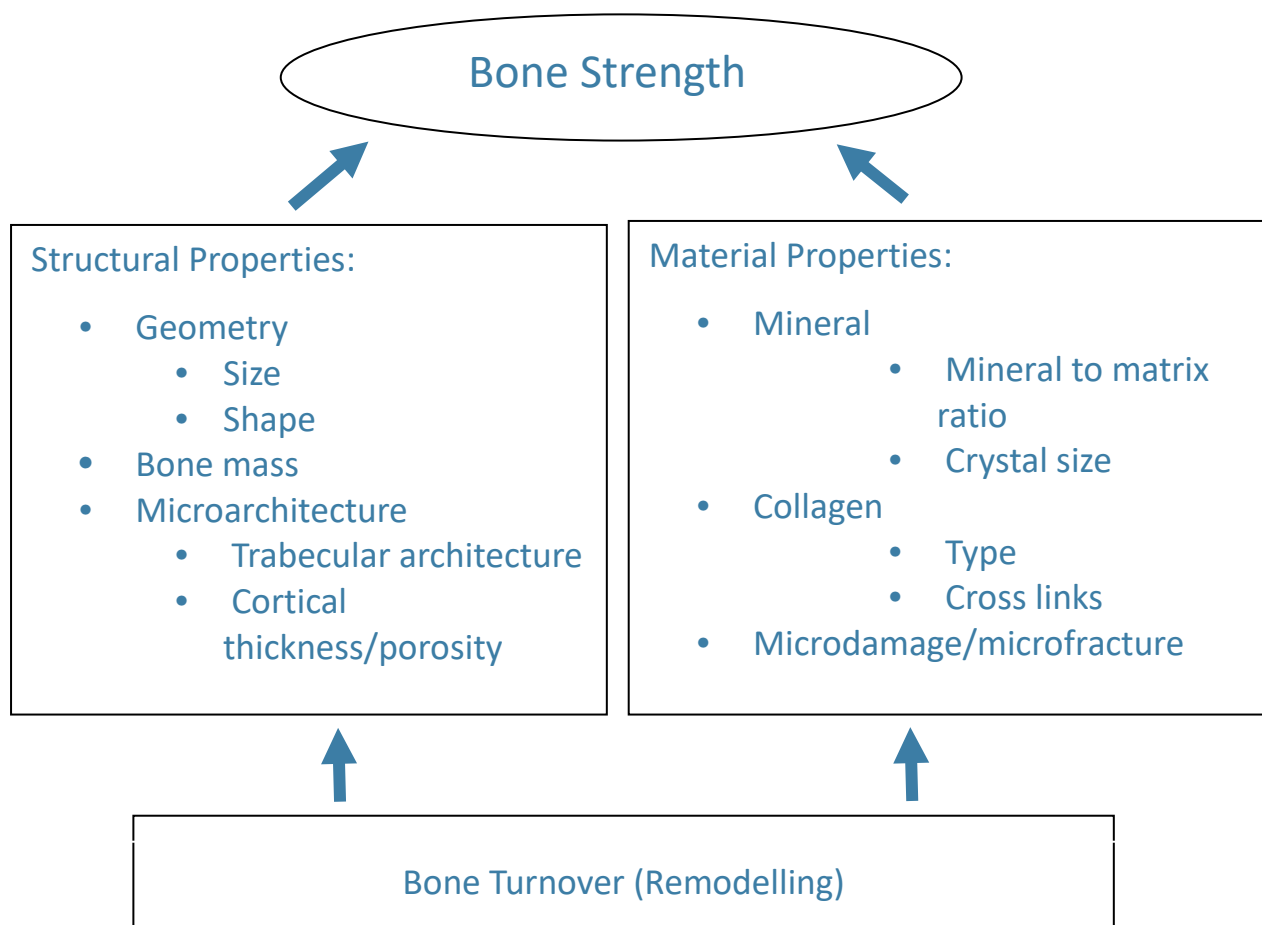

1 Physiology of healthy bone

The skeleton is a metabolically active tissue populated by a diversity of active cells that constantly remodel bone tissue throughout life. These cells activity - including cytokines and hormones production - is essential for various metabolic pathways in the whole body.

1.1 Biomechanical properties of bone

The strength of bone, that is, the ability of bone to resist fracturing, is determined by its structural and material composition, and by the activities of bone cells that determine the level and balance of bone turnover and ability to repair damage (box 1). Bone must be stiff and able to resist deformation, making loading possible. Bone must also be flexible to absorb energy by deforming: to shorten and widen when compressed, and to lengthen and narrow in tension without cracking. If bone is too brittle, the energy imposed during loading will be released by structural failure, initially by the development of microcracks and then by complete fracture. If bone is too flexible and deforms beyond its peak strain, it will also crack and fracture. Furthermore, bone must also be light to facilitate movement, and give room to its host tissue, the haematopoietic cells.

Box 1 Bone strength is related to structure, mass, material properties and turnover

1.2 Macroscopic organisation of bone

The skeleton includes the axial skeleton, with the vertebrae, the pelvis and other flat bones such as the skull and sternum; and the appendicular skeleton, including all the long bones.

Long bones, e.g., the femur and the humerus, include the diaphysis, with the epiphyses at their extremities. In the diaphysis, the cortical bone (cortex) surrounds the medullary canal. Epiphyses have a thinner cortex and the central area of the bone is filled with trabecular (cancellous) bone. The outer bone envelope is the periosteum, including neurofibres, blood and lymph vessels. The internal surface of cortical bone is called the endosteal surface. The metaphysis is the limit between the diaphysis and the epiphysis, where the growth plate is located in growing children. Although bone length growth stops with growth plate fusion, a slow process of increase in bone width continues throughout life, as a mechanical adaptation to cortical thinning due to aging.

In short, flat and irregular bones, cortical bone surrounds trabecular bone, embedding bone marrow. The periosteal and endosteal surfaces are comparable to that of long bones.

Cortical bone, represents 80% of adult bone mass, and trabecular (cancellous) bone 20% of bone mass.

Trabecular bone has a high surface/bone mass ratio and is in close contact with bone marrow, which is the source of bone cell precursors (figure 1).

Figure 1 Cortical and trabecular bone.

Cortical bone is mainly found in the shafts of long bones (e.g., femur) and the surface of flat bones (e.g., ribs). It consists of overlapping parallel osteons surrounded by interstitial bone and many lacunae containing

osteocytes, which are connected to each other and with the surface cells by numerous canaliculi. These osteocytes are concentrically distributed around the central Haversian canals, which contain blood vessels, lymphatic vessels and connective tissue. Long bones act as levers for loading and movement, with rigidity favoured over flexibility. The presence of a marrow cavity, which hosts haematopoietic cells, ensures structural stiffness and lightness. Cortical bone should not be called 'compact' bone as it is traversed by a huge number of canals (Haversian, Volkmann); these canals provide a large surface area for remodelling. In vertebrae, the cortical shell is very thin, but may bear up to 45–75% of the axial load. At the femoral neck, the cortical compartment is the main contributor to the bending rigidity; removal of trabecular bone from the femoral neck only reduces failure load by 7%.

Trabecular bone is found at the end of the long bones, in the inner part of flat bones and the vertebral bodies. It is a sponge-like, porous structure that functions more like a spring in that it can deform to absorb energy. The interconnecting trabecular plates are orientated according to lines of stress, which favour structural flexibility over stiffness.

1.3 Microscopic organisation of bone

Bone texture

We can distinguish two types of bone textures: woven bone and lamellar bone. Woven bone includes disorganized big collagen fibres and is found in foetal bone, ear ossicles, transiently in fracture callus, and in some conditions like Paget disease of bone and dense bone metastasis. In contrast, in lamellar bone, collagen fibres are organized in lamellae. Within each lamella, fibres are parallel, but form angles around 90° with adjacent lamellae, which is responsible for bone resistance.

Organization of cortical bone

Bone structural units (BSU) correspond to concentric lamellae, surrounding the Havers canal, which contains blood vessels. These canals communicate with transverse canaliculae, the Volkman canals. This cylindrical structure including the Havers canal with its lamellae, is also called an osteon. They lie within interstitial bone, which results from partial osteon remodelling.

Organization of trabecular bone

Trabecular bone is a dense tridimensional network. Bone remodelling produces bone packets, reminiscent of the cortical osteon structure, but open to the bone marrow.

1.4 Bone matrix

The organic bone matrix consists predominantly (90%) of type I collagen. Other non-collagenic proteins include proteoglycan, osteocalcin and osteonectin. Bone matrix also contains growth factors, such as IGF-I and II, for which bone tissue is the largest reservoir. Each unit of collagen is formed as pro-collagen within the osteoblast and consists of two α -1 chains and one α -2 chain twisted together in a triple helix. The formation of cross-links results in the assembly of the triple helix collagen molecules into stable collagen fibrils, which are further grouped into collagen fibres. Collagen fibres are laid down in a regular lamellar (layered) way, - the lamellar bone - and so contribute to the flexibility of bone.

1.5 Bone mineral

Calcium hydroxyapatite is the main bone mineral and is deposited along the lamellar gaps between collagen fibres. Mineralisation occurs in two phases: an initial phase in which more than 70% of the collagen matrix is mineralised within a few days (primary mineralisation), and a slower, prolonged phase lasting 3–6 months or more, characterised by the maturation of mineral crystals associated with changes in their size, composition and structure (secondary mineralisation). The degree and heterogeneity of mineralisation are two strong determinants of bone stiffness, thus contributing to bone strength.

1.6 Bone cells

Bone consists of four types of cells: osteocytes, osteoclasts, osteoblasts and lining cells. Osteocytes represent the largest number of bone cells (> 75%). Osteoclasts and osteoblasts are few in number and only present at locations with active bone turnover. They are resident cells (as are lining and periosteal cells) and are present throughout the entire bone.

Osteocytes, by far the most abundant bone cells, are derived from osteoblasts lying in lacunae after being embedded in the bone matrix during bone formation. They are small, flattened cells located within the bone matrix, which are connected to one another and to the lining cells on the bone surface by cytoplasmic extensions along tiny canals called canaliculi (some 50 per cell; figure 5). These cells have several functions:

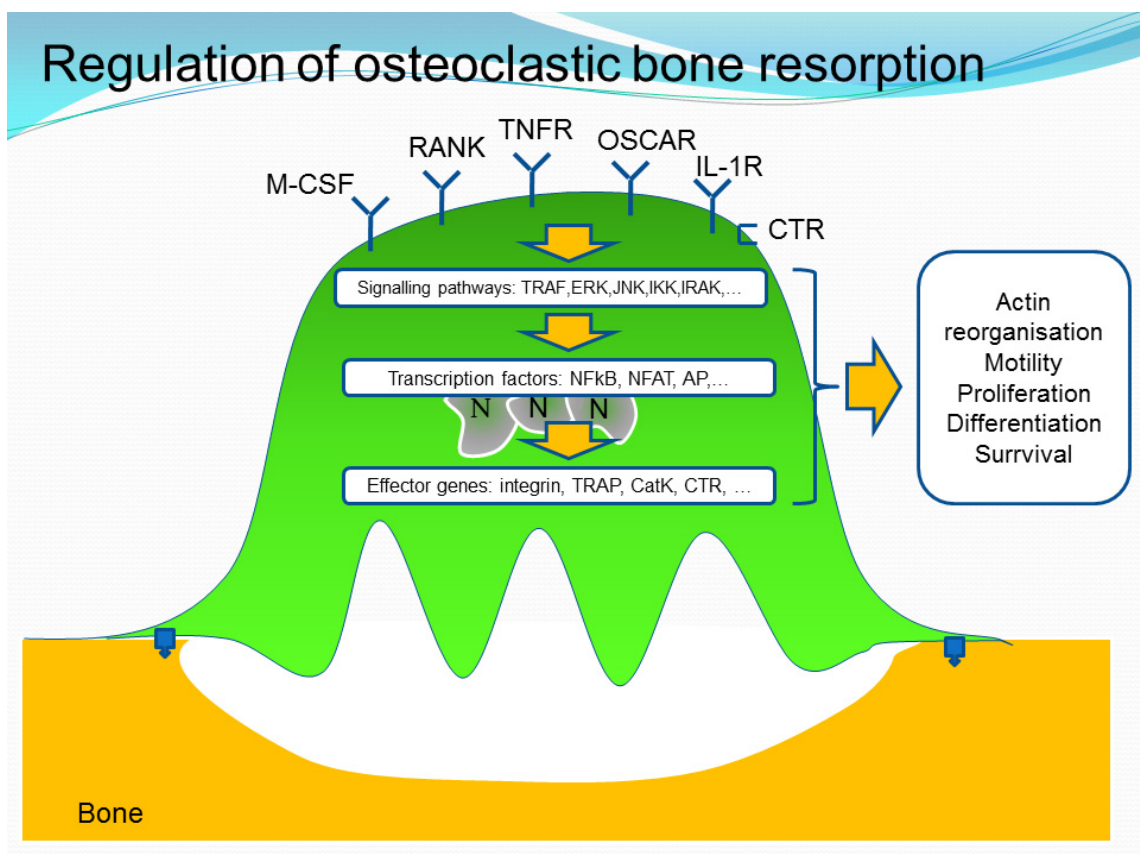

Figure 2 The osteocyte. (Source: Wikimedia Commons, http://en.wikipedia.org/wiki/File:Transverse_Section_Of_Bone.png)

- Osteocytes have an endocrine function by producing hormones, such as FGF23 (which regulates serum phosphate).
- They are the main source of regulators of bone formation (sclerostin, Dkk1) and bone resorption (RANK L).
- Osteocytes are very important in guarding the integrity of the material and structural strength of bone. They sense mechanical strain by mechanically induced cell deformations and/or fluid flows in the canaliculi, thereby signalling the need for adaptive remodelling and distribution to accommodate prevailing loads. The death of osteocytes by apoptosis precedes osteoclastogenesis. Osteocyte apoptosis—which is one of the characteristics of oestrogen deficiency, GC therapy and advanced age—has a more deleterious effect on bone strength than on bone mass.

Osteoclasts are giant multi-nucleated cells that are derived from haematopoietic precursors of the monocyte–macrophage lineage. They are the only cells that are able to resorb mineralised bone tissue. The first part of this process is their attachment to bone mediated by proteins including integrins, osteopontin, fibronectin, collagen and bone sialoprotein. Once attached to bone, they polarise, forming a specialised cell membrane, the ‘ruffled border’, which increases the surface area interface for bone resorption (figure 2). This resorption follows two steps:

Figure 3 The osteoclast. (Top) Activities: binding to bone, and secretion of acid, cathepsin K and metalloproteinases. (Bottom) Receptors for regulators of osteoclast activities activate intracellular signalling pathways, transcription factors and effector genes. (Reproduced with permission of P Geusens.)

- The first step is the dissolution of the crystals. The osteoclasts generate hydrogen ions ($\text{H}_2\text{O} + \text{CO}_2 \rightarrow \text{HCO}_3^- + \text{H}^+$) through the ruffled border into the cavity, which acidifies the area below the cell and dissolves the mineralised bone matrix into Ca^{2+} , H_3PO_4 , H_2CO_3 and water. Hydrogen ions are pumped against a high concentration gradient throughout the cell to the opposite side, thanks to chloride canals.
- The second step is the degradation of the matrix: several lysosomal enzymes (collagenases), such as cathepsin K and matrix metalloproteases (MMP), are released to digest the organic components of the bone matrix (collagen and other proteins). Tartrate-resistant alkaline phosphatases (TRAP) further destroy the bone matrix degradation products.
- The bone resorption pattern consists in the classical resorption pits, but also in resorption trenches. Some osteoclasts move laterally, displacing their extracellular bone-resorbing compartment over the bone surface without disassembling and reconstructing it, thereby generating long trenches. Compared with pits, trenches display more aggressive characteristics: long duration (days), high erosion speed (two times faster) and long-distance erosion

The macrophage colony-stimulating factor (M-CSF) produced by osteoblasts and the receptor activator of the nuclear factor κB ligand (RANKL), which is expressed abundantly by osteocytes, are both indispensable for osteoclastogenesis. RANKL interacts with its receptor RANK, which is expressed on osteoclast precursors and on mature osteoclasts, and promotes osteoclast differentiation and activation. Osteoprotegerin (OPG), present in the bone micro-environment, is mainly secreted by osteoblasts and osteocytes. It is a decoy receptor for RANKL. OPG blocks the interaction of RANKL with RANK and thus acts as a physiological regulator of bone resorption (figure 3).

Many cytokines, 1,25-dihydroxyvitamin D_3 , oestrogens and other molecules are known to affect osteoclastogenesis and bone resorption by influencing the production of RANKL and OPG, thus regulating and affecting the RANKL/OPG ratio: (a) RANKL is upregulated by cytokines like IL-1 β , IL-6, IL-17 and tumour necrosis factor- α (TNF α); (b) 1,25-dihydroxyvitamin D_3 enhances RANKL production; (c) parathyroid hormone (PTH) and glucocorticoids (GCs) enhance RANKL and inhibit OPG production; (d) oestrogens and tumour growth factor (TGF) enhance OPG production; (e) interferon- γ inhibits RANKL-induced osteoclastogenesis; (f) lipopolysaccharide (LPS) enhances OPG production in gingival fibroblasts; (g) ATP up-regulates RANKL expression by human osteoblasts; (h) fibroblasts and activated T cells produce RANKL and the Th17 subpopulation has a key role in osteoclastogenesis; (i) T regulators decrease osteoclastogenesis through CTLA4; and (j) interactions are possible between antibodies (as anticitrullinated protein antibodies) and osteoclastogenesis, through a Fc γ receptor on precursors cells surfaces.

Osteoblasts are plump cuboidal cells organised in continuous monocellular layers along the osteoid, and are derived from pluripotent stromal cells. They are responsible for the formation and mineralisation of bone

matrix. They synthesise and secrete growth factors, such as IGF-I and TGF β , into the matrix. Osteoblast differentiation and function is under the control of the Wnt signalling pathway (figure 4).

Figure 4 The RANK/RANKL/OPG signalling pathway. The mechanisms of action of (A) pro-resorptive and calcitropic factors and (B) anabolic and anti-osteoclastic factors. (Reproduced with permission from Boyle and Simonet, *Nature* 2003;423:337–42.)

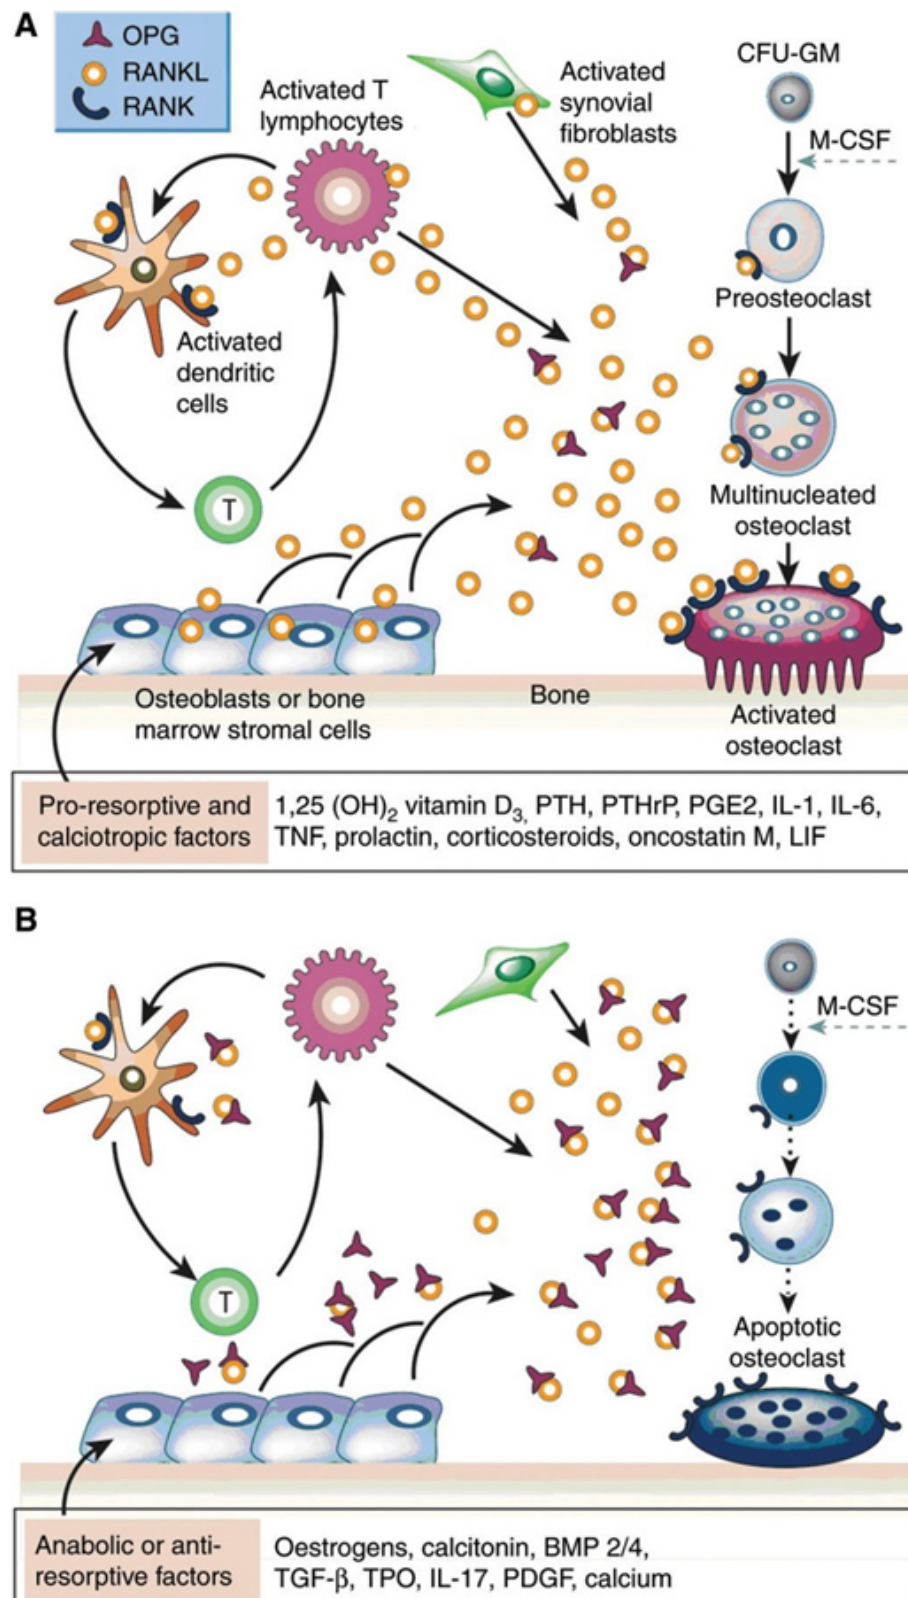

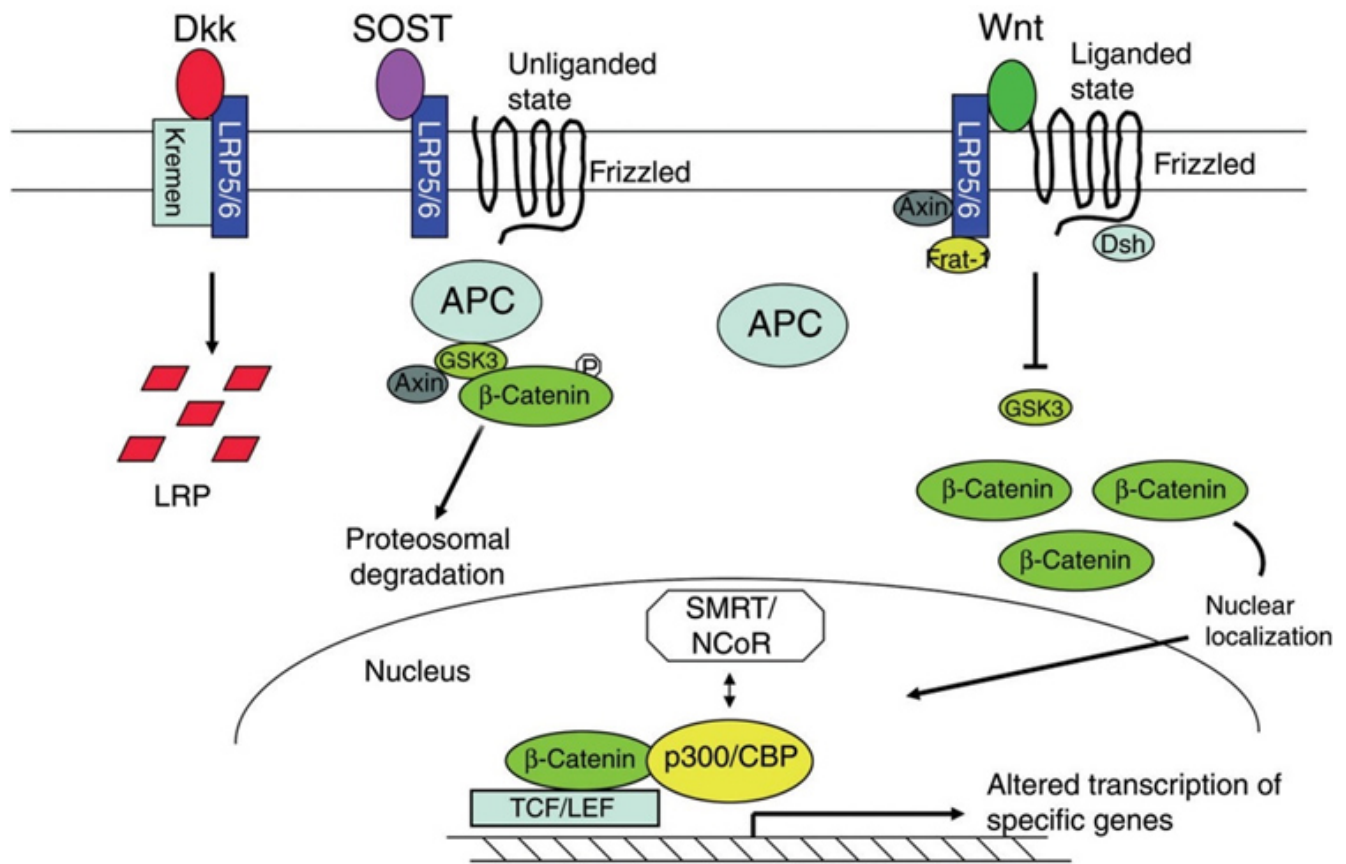

Figure 5 The Wnt signalling pathway in osteoblasts. (Reproduced with permission from Shoback, *J Clin Endocrinol Metab* 2007;92:747–53.)

In some family studies, high bone mass was found to be associated with mutations of LRP5, which had already been observed in animal studies (e.g., mutations in the Wnt signalling pathways are related to the absence of wings in fruit flies) (Krishnan *et al*, 2006*). Wnt molecules bind to the Frizzled receptor at the membrane surface, and need LRP5 as a co-receptor to stimulate osteoblasts by the canonical Wnt signalling pathway which involves β -catenin. Dkk1 (increased in multiple myeloma, rheumatoid arthritis (RA) and during GC treatment) binds to Kremen and LRP, which is internalised, and sclerostin (the protein from the SOST gene in osteocytes) binds to LRP5, thereby inhibiting Wnt from activating the canonical pathway. Thus, osteocytes can actively suppress bone formation through the production of inhibitory proteins, i.e., sclerostin and Dkk1, as inhibitors of the Wnt pathway.

Cross talk: at the local level cell activity is regulated by crosstalk between osteoblasts and osteoclasts.

Osteoblasts block bone resorption by production of semaphorin 3A, which inhibits RANK L-induced osteoclastogenesis, thereby preventing differentiation of monocytes to osteoclasts. Semaphorin 3A has also an autocrine effect on osteoblast differentiation. Moreover, direct contact of cells through ephrins (B₂ and B₄) is part of the crosstalk between osteoblasts and osteoclasts. In turn, osteoclasts secrete clastokines, such as sphingosine-1-phosphate (S1P) which is a coupling molecule. The initial resorption at the tip of the canal is

followed by a period where newly recruited reversal/osteoprogenitor cells and osteoclasts alternate, thus revealing the existence of a mixed "reversal-resorption" phase.

Lining cells cover the surface of the bone that is not remodelled. They are involved in the regulation of bone remodelling but their exact functions remain elusive.

1.7 Modelling and remodelling of bone

The cellular mechanisms responsible for the adaptation of bone are modelling (construction) and remodelling (reconstruction). Bones are shaped by modelling during growth, from the *in utero* period to adolescence, with chondrocyte differentiation, matrix synthesis and calcium deposition. In adults, bone is remodelled, with resorption of old bone and formation of new bone.

Bone modelling produces a change in the size and shape of bone. During this process, formation and resorption are uncoupled. Bone formation and resorption are then associated in time, location, quantity and balance. During bone remodelling, resorption by osteoclasts (lasting about 3 weeks) precedes bone formation by osteoblasts (over the following 3–4 months) through a coupled phenomenon. Osteoclasts and osteoblasts form the bone multicellular unit (BMU) that reconstructs endocortical, intracortical and trabecular bone. At the surface of trabecular bone, the BMU is covered with a canopy, through which passes a capillary that can deliver osteoblasts and osteoclasts, which have been recruited and differentiated from stem cells in the surrounding bone marrow.

During childhood and adolescence, both processes (modelling and remodelling) are involved in establishing peak bone mass (PBM), bone density, macro- and micro-architecture and strength. Bones grow by periosteal apposition (growth in width) and by endochondral ossification in the growth plate (growth in length). During childhood, modelling occurs primarily on the outer (periosteal) surface and is responsible for bone size. Resorption is essential for the excavation of a marrow cavity and the fashioning of cortical and trabecular bone. At puberty, bone thickens because formation can occur on both the outer and the inner (endocortical) surfaces. The modelling and remodelling rates decrease as longitudinal growth ceases with epiphyseal closure.

In young healthy adults, the resorptive phase of the remodelling cycle removes damaged bone, and the formation phase restores the structure. Each cycle is balanced and lasts 90–130 days. Bone resorption and formation are tightly coupled in time, location and quantity. After the remodelling cycle is achieved, mineralisation of new bone will continue. This constant bone turnover is essential: (a) for bone health, preventing the accumulation of old bone, enabling repair of microdamage and changing bone architecture in response to repeated loading; and (b) to provide calcium for calcium homeostasis.

1.8 Building up PBM

Peak bone mass is the amount of bone acquired at the end of skeletal growth, and it is followed by bone loss throughout the rest of life. Bone mass at a given age is a function of the achieved peak bone mass minus the amount of bone lost later as a consequence of menopause and aging; so the level that can be achieved at the end of bone growth is critical for the future risk of fracture. Peak bone mass, which is reached in early adult life, primarily depends on genetic factors. It is also influenced by dietary calcium intake during adolescence, possible toxic factors such as smoking, drugs and alcohol consumption, as well as by physical activity.

Blacks achieve higher peak bone mass than whites do, who have greater peak bone mass than Asians, particularly Japanese. Twin studies have shown a strong correspondence of peak bone mass in monozygotic twins, who have closer concordance in BMD than dizygotic twins do. Twin and family studies have consistently found that genetic factors account for up to 80% of BMD inter-individual variance. Searches for candidate genes have found that the collagen I α 1 Sp1 polymorphism is moderately associated with BMD and fracture, as shown in a meta-analysis of 13 studies involving 3642 patients. More recently, some variants of LRP5 have been found associated with BMD and fracture. After the candidate gene approach, genome-wide associations studies (GWAS), have helped with identifying genes involved in the regulation of bone strength. Current results from GWAS indicate that genes involved in the RANK–RANKL–OPG pathway (*TNFRSF11B*, *TNFRSF11A* and *TNFSF11* genes), the Wnt– β -catenin pathway (*LRP5*, *LRP4* and *SOST* genes), the oestrogen endocrine pathway (*ESR1* gene) and the 1p36 region (*ZBTB40* gene) are those most strongly associated with osteoporosis. These genetic variants, however, have modest effect sizes, so that we need to better understand the interactions between genes and the environment before they can be tested routinely to assess fracture risk. Building genetic risk scores combining a number of genes to predict fracture may a sensible approach. Dietary calcium intake may be important for attaining optimal peak bone mass. A few placebo-controlled trials in children or in adolescents, including one performed in twins, have shown a modest, but significant increase in BMD in those receiving calcium supplementation. Children with very low calcium intake are more likely to benefit from an increase in calcium intake, preferably from dietary source. A combination of increased physical activity and calcium intake may be more efficient than any factor alone to optimize bone gain during growth. Exercise during growth may contribute to the level of peak bone mass. It has been shown that intensive exercise before puberty may enhance bone acquisition, which might persist in adulthood, but the role of exercise in the normal physiologic range is unknown. In girls, areal BMD gains stop around ages 16-20 and in boys around ages 20-22. During pregnancy, diet, physical activity and toxic substances exposure, including cigarette smoking, may also influence the level of peak bone mass, via the long-term influence of epigenetic regulation.

1.9 Bone loss after menopause and during ageing

Bone loss is an inevitable consequence of ageing at the time of the menopause and continuing throughout life in both men and women, and is the result of persistent hypogonadism in women, emerging hypogonadism in some men, aging and senescence of bone cells and the secondary hyperparathyroidism in the elderly of both sexes that is associated with calcium and vitamin deficiency and reduced mobility (figure 6). It is estimated that approximately 50% of trabecular and 35% of cortical bone is lost over a lifetime in women, with losses in men approximating two-thirds of these amounts. However, keeping in mind that cortical bone is predominant in the skeleton, this means that most of the loss occurs in the cortical compartment.

Figure 6 Changes in bone mass with age.

At the cellular level, two forms of bone loss can be recognised. First, there is an increase in the number of bone remodelling units on bone surfaces, thus increasing the amount of bone undergoing resorption at any one time (increased activation frequency). More densely mineralised bone is removed and replaced with younger, less densely mineralised bone, reducing material stiffness. Excavated resorption sites remain temporarily unfilled and there is alteration of cross-linking between adjacent collagen fibres. Second, bone resorption is more pronounced, resulting in perforations of trabeculae (Seeman and Delmas, 2006*).

In addition, there is a third remodelling imbalance due to age: bone formation is reduced compared with resorption within each remodelling unit. As a result, bone may become too flexible, bend excessively and crack under usual loading conditions.

Since there are a lot of remodelling sites per unit of trabecular bone volume, a great portion of trabecular bone is turned over and lost (trabecular thinning). The deep resorption cavities result in a loss of trabecular

plates and their connectivity, causing greater deficits in bone strength. With continued remodelling, trabeculae perforate and some disappear completely, and remodelling is more active on the endocortical surface. That is why the role of cortical bone loss becomes more and more important with age. Cortical thinning (related to the resorption in the endocortical area) and porosity reduce the resistance of bone to the propagation of cracks. Periosteal apposition partly offsets the loss of cortical bone, more so in men than in women (Zebaze *et al*, 2010*).

1.10 Bone as an endocrine organ

It has been shown in animal models that there is coordinated regulation of bone mass, energy metabolism, and at least in males, fertility. Bone produces at least two hormones, FGF23 that regulates phosphate metabolism and osteocalcin that is involved in insulin sensitivity, energy expenditure and stimulates testosterone synthesis. By its biological connections with the brain, the kidney, the gut and the pancreas, bone physiology is linked to several chronic diseases, that in turn, also influence the skeleton.

2 Pathophysiology of osteoporosis

2.1 Definition and appropriate use of the T-score

The term osteoporosis originally referred to 'porosity of bone', one of the characteristics of bone that contributes to bone's failure to resist fracturing. In 1994, osteoporosis was defined by the WHO as 'a generalised bone disease characterised by a decreased bone mass and a deterioration of bone microarchitecture resulting in an increased fracture risk' (World Health Organization, 1994*). Finally, the National Institute of Health (NIH) defined osteoporosis in 2001 as 'a disease of compromised bone strength, resulting in an increased risk of fracture' (NIH, 2001*). Thus, osteoporosis is both a *disease*, and a *risk factor* for fracture.

Bone strength reflects the combination of bone mass and bone quality. Since there is no current direct and accurate means to measure either bone strength or bone quality, bone mass, assessed as BMD, which accounts for ~70% of bone strength, is used to assess osteoporosis. For epidemiological purposes, osteoporosis has been defined by the WHO as a BMD lower than -2.5 SD below the mean peak BMD in young healthy adults of the same gender, also known and expressed as the T score. This T score definition of osteoporosis (T less than or equal to -2.5) is operational and is the basis of our daily practice in the field of bone diseases.

Thus, to use T-scores appropriately, physicians must understand their disadvantages and shortcomings:

- a) The amount of bone is measured by dual energy X-ray absorptiometry using two-dimensional projection, and BMD is expressed in g/cm^2 , whereas density is expressed in cm^3 .

- b) The bone mass and density measurements do not measure the qualitative parameters of bone, and thus do not reflect all components that contribute to bone strength.
- c) As a consequence, more than half of patients who experience fragility fracture have a T-score above -2.5 ; this is related to the low sensitivity of BMD, and to the association between BMD and risk, which is continuous and does not have a biological threshold. This threshold has been defined on an epidemiologic basis, not on a bone strength estimation (that could be done nowadays by finite element analysis in each individual)
- d) Moreover, T-score calculation was proposed in order to clarify the characteristics of subjects included in clinical studies. Thus the choice of thresholds is arbitrary. The threshold of -2.5 SD below the mean BMD (at the femoral neck) in young subjects produces a 17% prevalence of osteoporosis among women aged 50 years and older, which is similar to the 15% lifetime risk of hip fracture for 50-year-old white women in the USA. Osteopenia has been defined as a T score between -1 and -2.5 , but there is no rationale for the threshold of -1 . The term osteopenia was created to allow comparisons among clinical and epidemiological studies. Osteopenia is not a disease and there is little evidence that it is a risk factor for osteoporosis (i.e., T-scores below -2.5). Osteopenia is frequently seen in patients with fractures (see below). Obviously the threshold for therapeutic decision making is different from the threshold for defining osteoporosis.
- e) The T-score is independent of age, as it refers to PBM, but the interpretation of the T-score for fracture risk is age dependent: for the same T-score, the fracture risk is higher in elderly women than in women in the early postmenopausal phase.
- f) The interpretation of T-scores is not intuitive: a woman with a T-score of -3 has a fracture risk twice that of woman with a T-score of -2 and four times that of a woman with a T-score of -1 , but it does not indicate her absolute risk.
- g) Falls (number, direction of falling, etc.) are of course key determinant of fracture, and independent of BMD.

Thus, the aetiology of osteoporotic fragility fracture is multifactorial and includes bone and fall related risk factors. A low BMD is a strong determinant of risk, but is not present in all patients. Those with prevalent fractures have the highest risk for future fracture.

Large-scale prospective population studies have enabled the identification of risk factors for fractures that are independent of low BMD and the quantification of their relative risks (RR) for predicting fractures. However, RRs are difficult to apply in daily clinical practice as their clinical significance depends on the prevalence of fractures in the general population. From this, and the observation that BMD measurements are not indicated

as a screening tool for the entire population (because of its low sensitivity), the concept of the absolute risk (AR) of fracture has emerged and refers to the individual's risk for fractures over a certain period of time in the context of a more global evaluation of fracture risk. One way of doing this is to use the FRAX case finding algorithm, which will be discussed in section 4 below.

Thus, the diagnosis of osteoporosis can be made on the basis of:

- T score below -2.5 ,
- and/or presence of non-trauma fractures (hip, vertebral...),
- and/or an elevated risk of fracture calculated in AR (such as with the FRAX tool).

Then a decision about treatment can be made, also based on the clinician's judgement concerning the individual risk for the patient, and the benefit of the treatment.

2.2 Postmenopausal osteoporosis

Oestrogen deficiency has been associated with osteoporosis since first suggested by Fuller Albright in the 1940s. It is the main cause of bone loss in women after menopause. Premature menopause—natural or surgically induced—extends the period during which a woman is exposed to a hypogonadal state, thus increasing the total duration of bone loss occurring after menopause.

Oestrogen deficiency is associated with an increase in the activation frequency of bone turnover, resulting in bone loss and structural decay (Rachner *et al*, 2011*). The production of cytokines (IL-1, IL-6 and TNF α) is up-regulated, which, in turn, increases the lifespan and production of osteoclasts. The balance between RANKL and OPG is changed: RANKL is up-regulated, while OPG is down-regulated. Of note, the elevation of FSH linked to oestrogen deficiency may have a direct role in bone loss.

Deeper erosion of bone results in severe loss of trabecular elements, making these trabecular elements less well connected and weaker. On the other hand, loss of oestrogen shortens the lifespan of osteoblasts and osteocytes. This results in the accumulation of apoptotic osteocytes within bone, which may increase bone fragility because of impaired detection of microdamage and suboptimal repair of bone, and may decrease the degree of bone mineralisation. Increased activation frequency has been found until 15 years after the menopause. In many elderly subjects, however, bone turnover, especially bone formation, is low.

2.3 Secondary osteoporosis

The term 'secondary osteoporosis' refers to bone loss, low BMD and increased fracture risk induced by diseases and some medications (table 1). Many patients referred for DXA have known risk factors. However, in the clinical context of DXA referrals, >30% of apparently healthy women with osteoporosis on DXA have

previously unknown secondary osteoporosis. The prevalence of secondary osteoporosis is even more frequent in patients with a recent clinical fracture.

Therefore, screening for secondary causes is indicated in all patients with osteoporosis and in patients with a recent clinical fracture. This includes a thorough history and physical examination and laboratory screening including as a minimum:

- serum calcium, phosphate and albumin: high calcium levels can be found in patients with malignancy and in patients with primary hyperparathyroidism; low calcium levels can be found in patients with osteomalacia.
- alkaline phosphatase: high levels can be found in patients with malignancy, Paget's disease and severe osteomalacia. Hypophosphatasia is very rare but is a contra-indication to anti-resorptive drugs.
- thyroid-stimulating hormone (TSH): hyperthyroidism can be asymptomatic.
- 25-hydroxyvitamin D: to screen for vitamin D insufficiency or deficiency.
- full blood count, erythrocyte sedimentation rate (ESR), and immunoelectrophoresis in case of possible multiple myeloma.
- kidney function must be assessed before prescribing anti-osteoporotic drugs.

Upon indication, other laboratory measurements can be performed, for example:

- PTH
- testosterone levels (in younger men with low bone density)
- tissue transglutaminase antibodies (coeliac disease).
- Serum tryptase (mastocytosis)
- Serum iron, ferritin (haemochromatosis)

Furthermore, X-rays of the spine are indicated when vertebral fractures are suspected (height loss, back pain, etc.). MRI, X-rays and bone scintigraphy are needed when bone metastases are suspected.

In rare situations with severe osteoporosis in individuals younger than 50 but without aetiology after screening, a transiliac bone biopsy for histomorphometric analysis may be performed.

Table 1 Some causes of secondary osteoporosis

Endocrine	Thyrotoxicosis
	Hyperparathyroidism (frequent)
	Cushing's syndrome
	Insulin-dependent diabetes mellitus
	Acromegaly
Hypogonadal	Anorexia nervosa
	Hyperprolactinaemia
	Hypogonadism (Turner and Klinefelter syndrome)
	Bilateral oophorectomy or orchidectomy
Drugs	Glucocorticoids (frequent)
	Aromatase inhibitors, GnRH agonists
	Antidepressants (selective serotonin recapture inhibitors)
	Antiepileptic drugs
	Proton pump inhibitors
Haematological disorders/malignancy	Multiple myeloma (frequent)
	Mastocytosis
	Haemophilia
	Thalassaemia
Nutritional and gastrointestinal disorders	Inflammatory bowel disease (frequent)
	Malabsorption syndromes (coeliac disease)
	Malnutrition
	Gastrectomy
Neurological disorders	Parkinson's disease
	Stroke
	Muscular dystrophy
Other disorders	Rheumatoid arthritis (frequent)
	Ankylosing spondylitis (frequent)
	Chronic obstructive lung disease (frequent)
	Systemic lupus erythematosus
	Chronic renal failure (frequent)
	Immobilisation
	Sarcoidosis
	Amyloidosis
	Haemochromatosis
	Pregnancy-associated osteoporosis
	Organ transplantation

2.4 GC-induced osteoporosis

GC-induced osteoporosis (GIOP) is the most common type of iatrogenic osteoporosis, and a frequent cause of secondary osteoporosis. Approximately 1:200 (0.5%) of the population may be exposed to GCs for a period of at least 3 months. Observational data suggest that 30% of individuals taking long-term GCs for more than 3 years will have evidence of osteoporotic fractures.

From epidemiological studies there is evidence that the increased risk of osteoporotic fractures is:

- proportional to the cumulative GC dose; the risk increases after 3 months of therapy associated with
- increased bone loss, most pronounced in the first year and
- likely to be associated with even low doses of GCs.

Yet few patients taking GCs are evaluated for their skeletal health or receive specific preventive or therapeutic agents.

The pathogenesis of GIOP is a result of several mechanisms. This issue is discussed in depth elsewhere in this module.

2.5 Osteoporosis in inflammatory systemic disorders

There is an increased risk of osteoporosis in patients with RA as well as other rheumatic conditions such as ankylosing spondylitis (AS) and systemic lupus erythematosus (SLE) (see the in-depth discussion on RA and AS elsewhere in this module). Disease activity, immobility and treatment are factors that increase the risk of osteoporosis and fractures, in addition to the background fracture risk. Bone resorption is increased by inflammation and involves many cytokines, such as TNF α and interleukins, RANKL/OPG and Dkk1.

The risk of osteoporotic fractures or low BMD is increased in some SLE patients, since several risk factors may accumulate in these individuals: the use of GCs, female gender, vitamin D deficiency due to sunshine avoidance, chronic kidney disease, amenorrhoea and immobility. Obviously, the use of GCs is one of the most important causes of osteoporosis in patients with SLE. In several cross-sectional studies, it has been found that trabecular and cortical BMD were lower in SLE patients than in healthy controls. In a study from a reference centre in Amsterdam, vertebral deformities were found in 20% of patients, which is remarkable given that the mean age of the patients was only 41 years. It cannot be excluded that, with increased life expectancy for SLE patients treated with GC, combined with other immunosuppressive drugs, the incidence of osteoporotic fractures will increase in (elderly) patients with SLE.

The situation in patients with other systemic inflammatory diseases, such as vasculitis and specifically giant cell arteritis which concerns elderly, is analogous to that in SLE patients. There is no data on fracture incidence,

and BMD may be decreased in particular in GC-treated patients. Since bone loss is highest early in the disease, probably related to a high initial dose of GCs and high initial inflammatory activity, screening for osteoporosis in these patients is mandatory so that anti-osteoporotic drugs can be prescribed early, if appropriate.

2.6 Osteoporosis in men

Fractures are more prevalent in men than in women from childhood to middle life, probably because of a higher incidence of trauma. After 40 years of age, fractures are less common in men than in women, but the incidence of fracture as a result of mild trauma increases with aging. The lifetime risk of fracture in men older than 50 years is estimated to be 20%. Fracture risk in men increases from 50 years onwards for vertebral fractures and from 65 years onwards for hip fractures. A key issue is that mortality rates after hip fracture are higher in men than in women, and are related to pre-fracture health status (comorbidities) and post-fracture complications. The prevalence of fractures is lower in men than in women. After the age of 50 years, the incidence of vertebral fractures is about one third to one half of that in women. When assessing the prevalence of vertebral fractures in men, the consequences of trauma at younger ages must be kept in mind.

As in women, osteoporosis in men can result from an inadequate peak bone mass and/or accelerated bone loss. Men build up bigger bones than women, this larger bone size being responsible for the higher bone strength. During aging, bone size may increase in men more than in women by periosteal apposition, increasing even further the gender difference in bone size established during growth (figure 7). Cortical bone loss is less in men because endocortical resorption and cortical porosity are lower. Trabecular bone loss is similar, but trabecular architectural disruption is less in men than in women. Specifically, in aging men, the trabeculae are thinner, whereas they are perforated in postmenopausal women. These structural differences are presumably not captured by measuring BMD, as the absolute risk for fractures appears to be no different between men and women of the same age and BMD, so that the diagnostic threshold for osteoporosis in women can be used in men.

Unlike women, men have no midlife drop in sex hormone production and, thus, no midlife increase in remodelling rate. The andropause occurs at a later age than the menopause in women and only in a subpopulation of men. Aging in men is accompanied by a progressive, but individually variable decline in serum testosterone production: more than 20% of healthy men over 60 years of age present serum levels below the range for young men. Albeit the clinical picture of aging in men is reminiscent of that of hypogonadism in young men and decreased testosterone production appears to play a role in some of these clinical changes in at least some elderly men, the prevalence of androgen deficiency and its association with structural abnormalities is not unequivocally established. In fact, minimal androgen requirements for elderly men remain poorly defined and are likely to vary between individuals. Consequently, borderline androgen deficiency cannot be reliably diagnosed in the elderly.

Hypogonadism is a risk factor for osteoporosis in women. However, as mentioned above, the definition, prevalence, causes and structural consequence on bone of late onset hypogonadism in men are inadequately defined.

Figure 7 Summary of growth and age-related changes in axial and appendicular skeletal mass, size and density in men and women.

In contrast to women, in whom postmenopausal and age-associated osteoporosis is the most frequent cause of fractures, many men with osteoporosis have other causes than hypogonadism and old age: use of GCs, alcohol abuse, current smoking, etc. Contributors to secondary osteoporosis are documented in up to 50% of all cases. A specific problem of secondary osteoporosis in men involves men treated for prostate cancer, in whom androgen ablation therapy results in accelerated bone loss. Idiopathic osteoporosis, defined as osteoporosis that occurs without any known cause of osteoporosis, has been described in men under the age of 70 years. Its prevalence, cause and natural course remain unclear, although the role of inadequate peak bone mass with smaller bones linked to delayed puberty, along with changes in IGF-1 effect have been suspected.

In contrast to the data available in women, there is a lack of data based on randomised placebo-controlled trials of anti-osteoporotic treatments using vertebral, hip or other non-vertebral fractures as an endpoint in men. An increase in BMD and a reduction in vertebral fracture risk has been reported in men with osteoporosis treated with bisphosphonates. PTH therapy in men causes BMD effects similar to those observed in postmenopausal women.

Only a few hundred elderly men have received androgen therapy in the setting of a randomised controlled study, and many of these men were not androgen deficient. The most consistent effects of androgen replacement treatment have been on body composition, but to date there is no evidence-based documentation of clinical benefits of androgen administration to elderly men with normal or moderately low serum testosterone in terms of diminished morbidity or of improved survival or quality of life (QoL). Until the long-term risk–benefit ratio for androgen administration to elderly men is established in adequately powered trials of longer duration, androgen administration to elderly men should be reserved for the minority of elderly men who have both clear clinical symptoms of hypogonadism and frankly low serum testosterone levels.

2.7 Osteoporosis in children and adolescents

Disorders of bone fragility associated with increased fracture risk in children can be divided into primary osteoporosis (osteogenesis imperfecta (OI), idiopathic juvenile osteoporosis (IJO) and osteoporosis pseudoglioma syndrome), where the defect is intrinsic to the bone tissue itself, and secondary osteoporosis (immobilisation-induced disease, inflammatory (rheumatic) diseases and the use of GCs, for example), where the defect arises in a tissue other than bone and adversely affects the skeleton.

In OI, 90% of cases have mutations in one of the two genes encoding type I collagen (COL1A1, COL1A2). The severity ranges from very mild to fatal. Affected individuals experience recurrent fractures resulting in bone pain, deformity and impaired function. The incidence is reported to be approximately 1 in 15 000–20 000. Detection of mild cases in otherwise unaffected families centres on the finding of additional clinical features such as ligamentous laxity, dentinogenesis imperfecta, delayed walking and blue sclerae. These features can also be sought in family members, along with hearing loss and heart valve prolapse. More severely affected children, in particular those with dentinogenesis imperfecta, are at risk of basilar invagination and hydrocephalus. Multiple crush fractures predispose to scoliosis, particularly in early childhood and at puberty. The diagnosis can be confirmed by the finding of a mutation in the type I collagen genes in approximately 90% of cases. Heterozygous mutations in LRP5 have been described in a few cases of juvenile osteoporosis, as well as in children with recurrent fractures and low bone mass. Homozygous mutations in LRP5 result in osteoporosis pseudoglioma syndrome, a severe bone disorder with additional eye defects.

3 Osteoporotic fractures

3.1 Fracture epidemiology

Osteoporosis is a significant health issue because of the fragility fractures and their association with increased mortality and morbidity. That also result in a considerable global economic burden. Osteoporotic fractures predominantly occur in the elderly, and life expectancy is increasing worldwide. The proportion of frail elderly persons at high risk of falls and fractures is expected to rise dramatically in the next decades; in some countries, the number of centenarians is increasing sharply. This has profound implications for societies and individuals who expect to reach old age in good health.

Even if age-adjusted incidence rates for hip fracture tend to decrease slightly in some countries (Western Europe, North America), the estimated number of hip fractures worldwide will rise from 1.7 million in 1990 to 6.3 million in 2050 (Svedbom *et al*, 2013*), due to the increase in the number of elderly at risk. Fractures of the hip, vertebrae and wrist have long been regarded as the typical osteoporotic fractures (table 2). However, the effect of osteoporosis on the skeleton is systemic, and prospective studies have shown that there is an increased risk of almost all types of fractures in individuals with low bone density. Moreover, adults who sustain a fracture are at substantially greater risk of having a subsequent fracture. The RR for a subsequent non-vertebral fracture is doubled after a non-vertebral fracture. After a vertebral fracture, the risk for another vertebral fracture is quadrupled, and the risk for a non-vertebral fracture is doubled. The incidence of vertebral fractures is much higher than that of wrist or hip fractures (figure 8). Some public health problems such as diabetes and obesity are risk factors for various fractures (without decreased BMD), and attention must be paid to the effects of these current epidemics on the epidemiology of fragility fractures.

Table 2 Estimated risks of fractures at various ages. (Reproduced with permission from Van Staa et al, Bone 2001;29:517–22)

	Current age (years)	Any fractures (%)	Radius/ulna (%)	Femur/hip (%)	Vertebral (%)
<i>Lifetime risk</i>					
Women	50	53.2	16.6	11.4	3.1
	60	45.5	14.0	11.6	2.9
	70	36.9	10.4	12.1	2.6
	80	28.6	6.9	12.3	1.9
Men	50	20.7	2.9	3.1	1.2
	60	14.7	2.0	3.1	1.1
	70	11.4	1.4	3.3	1.0
	80	9.6	1.1	3.7	0.8
<i>10-Year risk</i>					
Women	50	9.8	3.2	0.3	0.3
	60	13.3	4.9	1.1	0.6
	70	17.0	5.6	3.4	1.3
	80	21.7	5.5	8.7	1.6
Men	50	7.1	1.1	0.2	0.3
	60	5.7	0.9	0.4	0.3
	70	6.2	0.9	1.4	0.5
	80	8.0	0.9	2.9	0.7

Figure 8 Incidence of osteoporotic hip, vertebral and wrist fractures. (Modified from Van Staa et al, *Bone* 2001;29:517–22, including data from the European Prospective Osteoporosis Study (EPOS) Group, *J Bone Miner Res* 2002;17:716–24.)

3.1.1 Hip fracture

Hip fracture is the most serious consequence of osteoporosis in terms of disability (functional competence and physical functioning markedly diminish after a hip fracture), mortality (20–30% in the first year after fracture), and use of hospital and institutional care (Bliuc et al, 2009*) (box 2). The incidence rises from 1/1000 person-years at age 50–60 years to 30/1000 person-years at the age of 80 in women (0.5/1000 to 19/1000 person-years, respectively, in men). In Westernised countries, data suggest a decrease in the age- and sex-adjusted ratio of hip fracture, but absolute numbers are still increasing because life-expectancy is increasing.

Box 2 Consequences of hip fractures in women

- 20–30% of excess mortality within 1 year
- 20% severely impaired mobility after 1 year, requiring long-term nursing care
- 50% do not regain previous mobility

There is a substantial variation in hip fracture rates between populations. In general, people who live farther from the equator seem to have a higher incidence of fracture. The highest rates are seen in Caucasians living in northern Europe, especially in Scandinavian countries. The rates are intermediate in oriental populations and lowest in black populations. The lower incidence rates in the developing countries can be partially explained by lower life expectancy, but probably also by genetic factors associated with bones of higher quality. A hip fracture usually results from the co-occurrence of several risk factors: low bone mass, low bone quality, elevated fall risk, co-morbidity and high age. Data suggest seasonality in these fractures, which occur more frequently in spring, maybe because of reduced concentrations of vitamin D or increased physical activity after the winter. At least half of the hip fractures happen at home or in an institutional setting. Falls are involved in 80–90% of hip fractures; the others are the primary event, related to bone fragility, with fall thereafter.

3.1.2 Vertebral fracture

Vertebral fracture is the hallmark of osteoporosis, but its characteristics impede an accurate assessment of their epidemiology.

- A vertebral fracture is not always a binary phenomenon (fracture yes/no, as for a femoral fracture), but can be of graded severity. This grading is relevant in clinical practice (see below) and was quantified by Harry Genant in 1993 (figure 9). Mild, moderate and severe fractures are those with a decrease of 20–25%, 25–40%, and more than 40%, respectively, of one vertebral body height (either anterior or middle). The classification is based on visual estimation of the decrease, as compared to the expected height, the posterior height of the vertebra (if it is not deformed) or the adjacent vertebrae. This assessment is easy, reproducible and relevant for an appropriate assessment of osteoporosis.

Figure 9 Semiquantitative grading scale for vertebral fractures. (Reproduced with permission from Genant et al, J Bone Miner Res 1993;8:1137–48.)

In contrast, morphometric techniques, which use points positioned on the vertebral bodies for direct measurements of heights, must be avoided in clinical practice as they provide a lot of false positive and false negative results, related to the other causes of vertebral deformities.

- A vertebral fracture can occur without trauma or fall: 40% are related to falls but this proportion is lower in women aged 80 years and more. Vertebral fractures usually occur during daily activities such as lifting, climbing stairs or bending forwards. Neurological involvement after an osteoporotic vertebral fracture is very rare and must lead to a complete investigation for other causes of vertebral fractures (malignancy, etc.).
- A vertebral fracture can be responsible for acute back pain, but symptoms may be mild, and these fractures considered to be 'asymptomatic'. Actually it is estimated that only one third of vertebral fractures come to clinical attention at the time they occur. Loss of height is one of the characteristic of these fractures (figure 10) (Briot et al, 2010).
- Vertebral fractures are overlooked in radiographs. Lack of radiographic detection, and the use of ambiguous terminology (such as 'vertebral deformities') are the two main determinants for failing to

diagnose vertebral fracture. Fractures have to be differentiated from other conditions such as Scheuermann's disease, remodelling and deformities in osteoarthritis, and normal variations in vertebral body height (box 3).

Figure 10 Simple clinical investigation.

Box 3 Why vertebral fractures are often not recognised

- Diagnosing vertebral fractures is more difficult than non-vertebral fractures
- Vertebral fractures are often overlooked on radiographs
- The diagnosis of a vertebral fracture can be over-ruled by another diagnosis
- Missing the clinical relevance of diagnosing vertebral fractures

The prevalence of radiological findings increases with age. The rates vary between populations, with a demonstrated threefold variation across Europe and up to twofold variation within European countries in the European Vertebral Osteoporosis Study (EVOS). Geographical variation in the prevalence and incidence of vertebral fractures seems to be substantially less than that of hip fracture. The age-adjusted and sex-adjusted incidence rates for vertebral deformity are 1% per year among women and 0.6% per year among men from the European Prospective Osteoporosis Study. Similar figures have been found in the USA. The age-standardised population prevalence of vertebral fractures across Europe is 12.2% for men and 12.0% for women aged 50–79 years. In studies where radiographs are performed at baseline and then repeated during follow-up, the incidence of all vertebral deformities has been estimated to be three times that of hip fracture. In Europe, at age 75–79 years, the incidence of vertebral fractures defined in this way is 13.6 per 1000 person-years for men and 29.3 per 1000 person-years for women. This compares with 0.2 per 1000 person-years for men and 9.8 per 1000 person-years in 75–84-year-olds where the fractures were defined by clinical presentation in an earlier study from Rochester, Minnesota. The overall age-standardised incidence in EVOS was 5.7 per 1000 person-years in men and 10.7 per 1000 person-years in women.

Among postmenopausal women referred for BMD measurements, who have risk factors for osteoporosis but T scores above -2.5 , 20% have actually prevalent vertebral fractures. This proportion is higher when assessed at the time of a non-vertebral fracture, particularly in elderly women with a recent hip fracture.

Vertebral fracture assessment (VFA) is a densitometric technique which can be performed easily and quickly at the same time as a BMD measurement. It is important to notice that radiation exposure associated with image acquisition is dramatically lower than that for standard X-rays ($3\text{--}40\ \mu\text{Sv}$ vs $600\ \mu\text{Sv}$). Moreover, standard X-rays are obtained using cone beam X-rays which create parallax distortion within vertebrae located above and below the central point of the beam; VFA uses fan-beam technology and avoids this problem. However, the images obtained with standard spine radiography are less noisy, have a higher spatial resolution, and the legibility of the vertebrae of the upper thoracic spine is better with spine radiography.

3.1.3 Non-hip-non-vertebral fractures

Non-hip-non-vertebral fractures are the most frequent osteoporotic fractures; they carry an increased risk for subsequent fractures. The non-hip-non-vertebral fracture/hip fracture ratio is 20 in women aged 50–60 and 1.5 in the elderly. These fractures must not be neglected, because an opportunity to improve care of osteoporosis is missed.

Wrist fractures have a different pattern of occurrence from hip and vertebral fractures: there is a steep rise in incidence during the early postmenopausal period among women, but a plateau thereafter. In men, there is no apparent increase in the incidence of wrist fracture with age. The plateau may be due to the mode of falls: later in life, a woman is more likely to fall onto her hip than onto an outstretched hand as her neuromuscular co-ordination deteriorates.

The incidence rates of proximal humeral, pelvic and proximal tibial fractures rise steeply with age, and are higher in women than in men.

3.2 Consequences of fractures

Clinical features resulting from osteoporotic fractures include increased risk for new fractures (even within the short term), morbidity (pain, decreased QoL, physical impairment) and excess of mortality, especially after some fractures (table 3).

Fractures of long bones commonly result in acute pain with one or more clinical signs of fracture (swelling, haematoma, deformation, local crepitations, and localised pain on pressure) and are easily confirmed radiographically. Some fractures, such as stress fractures, are more difficult to diagnose, as local clinical signs can be confounded by arthritis or tendinitis, and other imaging techniques may be needed to identify them,

such as MRI and bone scintigraphy. The outcome is dependent on the fracture location, the presence of bone- and fall-related risks, and general health status and co-morbidities before and after the fracture.

Table 3 Clinical features of fractures (functional repercussions: +, yes; –, no)

	Hip	Vertebral clinical	Vertebral radiographic	Wrist
Excess mortality	++	+	+	–
Increased fracture risk	+	+	+	+
Pain				
Acute	+	+	+ or –	+
Chronic	–	+	+ or –	+
Functional decline				
Short-term	+++	+	+	+
Long-term	++	+	+	+
Psychosocial decline	++	+	+	–
Quality of life	+++	++	+	+

3.2.1 Fractures and the risk for subsequent fractures

Epidemiological studies show consistently that patients with different types of fragility fractures are at increased risk of developing subsequent fractures (Van Geel *et al*, 2009*). A previous vertebral fracture carries a 7–10-fold increased risk of subsequent vertebral fractures, a similar order of magnitude to the increased risk associated with sustaining a second hip fracture after a first. Data from Rochester, Minnesota suggest that the risk of a hip fracture is increased 1.4-fold in women and 2.7-fold in men after a distal forearm fracture. The corresponding figures for subsequent vertebral fracture are 5.2 and 10.7. The EVOS study demonstrates that a prevalent vertebral deformity predicts incident hip fracture with a rate ratio of 2.8–4.5. The Dubbo Osteoporosis Epidemiology Study in Australia demonstrated similarly increased rates of refracture in men and women over a 10-year period.

The risk of subsequent fracture is characterised by a time effect and a dose effect:

- *Time effect*: within a cohort of 4140 postmenopausal women in the Netherlands, 54% had refractured within 5 years and 23% had refractured within 1 year of an initial fracture. After the initial fracture, the RR of subsequent fracture declined with time: thus the RR of subsequent fracture in the first year after the initial fracture was 5.3, within 2–5 years it was 2.8, within 6–10 years it was 1.4, and it then dropped to 0.41 for more than 10 years after the initial fracture. Some 20% of postmenopausal women sustain an incident fracture in the year following a vertebral fracture. The risk of hip fracture (adjusted for age and BMD) decreases from 2 at 5 years to 1.4 at 10 years after a vertebral fracture.

Thus, subsequent fractures cluster in time after the first fracture. That means that there is a window of opportunity for treatment in the months immediately following an osteoporotic fracture.

- *Dose effect*: this has been shown consistently for vertebral fractures: the more the number of prevalent vertebral fractures, and the more severe they are, the higher is the risk of incident vertebral and non-vertebral fractures. Even the grade 1 fractures are associated with an increased short-term risk of vertebral fractures (not non-vertebral) in elderly women with low BMD.

3.2.2 Morbidity of osteoporotic fractures

Hip fractures are the most serious consequences of osteoporosis in terms of disability, use of hospital and institutional care, and mortality. They represent 20% of all use of orthopaedic beds in Western countries. At 1 year post fracture, more than 40% of patients cannot walk independently, and more than 50% cannot perform all activities of daily independent living. Age is a major factor here: the proportion of patients being discharged to nursing care is dramatically high in the elderly.

In clinically diagnosed *vertebral fractures*, pain onset varies from gradual to sudden and its intensity from minimal to severe lancing back pain. Pain worsens with movement, coughing or sneezing and is often not relieved by rest. However, pain is sometimes diffuse and not localised to the fractured vertebra. This acute, severe pain episode gradually subsides within 2–6 weeks. Chronic back pain can last for many years. Clinical and radiological vertebral fractures are associated with pain and also with hyperkyphosis, loss of spinal mobility, decline in function, mobility and muscle strength, and an increased risk of falls, bone loss, fractures and loss of independence. Hyperkyphosis results in the typical clinical presentation of a ‘dowager’s hump’. It is a risk factor for falls and subsequent fractures (Roux *et al*, 2010*).

Hyperkyphosis and height loss reduce the distance between the iliac crest and the ribs, resulting in problems with digestion and a protruding abdomen. Functional spine restrictions are associated with difficulty in dressing, fixing hair, standing, lying down, moving in bed, doing housework, walking, climbing stairs, washing, bathing, using the toilet and getting down to the floor, decreases in general health status measures, activities of daily living, balance capability, functional reach, mobility skills, 6-min walk and muscle strength, and a higher level of need for assistance. Lung function progressively decreases with increasing number of vertebral fractures and the degree of kyphosis, probably as a result of increased abdominal pressure.

The presence and number of vertebral fractures are associated with a decrease in QoL and its subdomains (pain, physical function, general health and physical mobility). Lumbar vertebral fractures lead to greater impairment of physical function than thoracic vertebral fractures. Psychosocial outcome is less well documented as many studies did not include a control group. Depression, which is a common mental health

problem in older people, is more frequent in women with osteoporosis and is related to the number and severity of vertebral fractures.

Much less emphasis has been placed on the consequences of *non-vertebral-non-hip* fractures, although their aggregate burden is substantial. Roughly 35% of all healthcare expenditure attributable to osteoporotic fractures in the USA are accounted for by these fractures. They result in more outpatient services than hip fractures. Decrease in QoL has been reported in patients with such fractures. Because they occur more frequently and in younger individuals than hip fractures, patients with these fractures can experience the harmful effects of their fracture for many years.

3.2.3 Mortality following osteoporotic fractures

Increased mortality after some osteoporotic fractures is well recognised, particularly for hip and vertebral fractures, and there is accumulating evidence of increased mortality risk following other types of osteoporotic fracture (mainly humerus and pelvis). Deaths are directly related to hip fracture in 24% of cases, and 28% of deaths among patients hospitalised for vertebral fractures are presumably attributable to the fracture itself. Comorbidities increasingly contribute to mortality as subjects become older and frailer (Bliuc *et al*, 2009*; Roux *et al*, 2012*).

For *hip fracture*, mortality is highest in the first year, and remains elevated in subsequent years. The age- and sex-specific standardised mortality ratios (in Dubbo, Australia) are increased and are 2.43 and 3.51 in women and men, respectively, with hip fracture. A meta-analysis provided data from 22 cohorts in women and 17 cohorts in men, and showed that the relative hazard for all-cause mortality was 5.75 in women and 7.95 in men in the first 3 months after hip fracture, and then decreased but did not return to the expected rates in age- and sex-matched controls. White women having a hip fracture at age 80 years have excess annual mortality compared to controls of 10% within 2 years after the fracture. Importantly, short-term mortality is also increased after a hip fracture in subjects aged less than 80 years.

Both prevalent and incident *vertebral fractures* predict increased mortality, even if the fractures are subclinical, that is they are diagnosed only by imaging. Physical frailty and pulmonary complications are associated with this excess mortality.

Finally, some *non-vertebral-non-hip fractures* (humerus, pelvis, but also lower extremity of the femur and higher extremity of the tibia) are responsible for a fracture–mortality association. A key observation is that refractures contribute substantially to overall mortality.

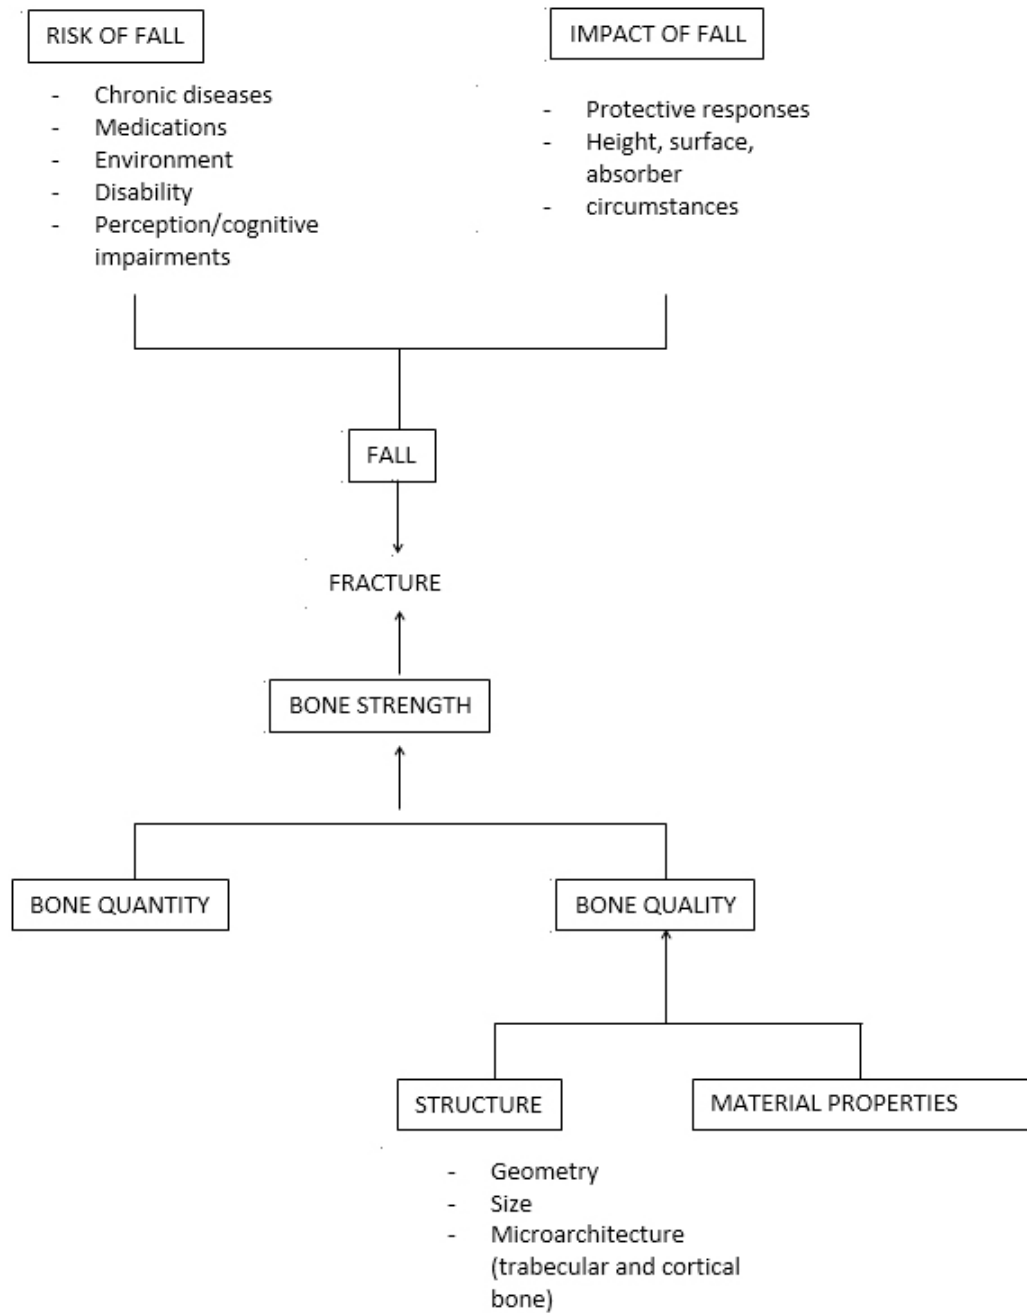

3.2.4 Few therapeutic consequences: the treatment gap

Despite this increased mortality and morbidity after osteoporotic fracture, most patients with fracture - especially severe fractures - do not receive adequate therapy thereafter. It has been shown as soon as the end of 1990s that, even after marketing of several effective therapies for osteoporosis, most patients who have sustained an osteoporotic fracture (forearm fracture, vertebral fracture and even hip fracture) did not receive adequate secondary prevention for future fractures, whereas the risk of repeated fractures is markedly increased, including that of vertebral and second hip fracture. Despite increased attention to this issue, the situation has not improved. In fact, over the past 10 years, the proportion of patients with fracture correctly treated has halved. Now, it is probably not higher than 20-25%.

4 Assessment of fracture risk

The aetiology of osteoporotic fragility fractures is multifactorial and includes bone- and fall-related risk factors, many of which are readily clinically recognisable before a fracture has occurred (figure 11) (Bours *et al*, 2011*). This is best illustrated in studies of risk factors for hip fracture that have shown that low BMD and fall risks are independent risk factors for hip fractures. Compared to controls, patients presenting with a clinical vertebral or non-vertebral fracture had a threefold higher risk for having BMD osteoporosis and a fourfold higher risk for having had a fall, and half of the patients with a recent fracture had both bone- and fall-related risks.

A large number of studies demonstrated that age, low BMD and prevalent fracture are the three main risk factors for sustaining a fracture. RR are difficult to apply in daily clinical practice as their clinical significance depends on the prevalence of fractures in the general population. From this observation and for the purpose of clinical application, the concept of the absolute risk of fracture has emerged and refers to the individual's risk for fractures over a certain time period, for example, over the next 5 or 10 years, a period in which data suggest that anti-osteoporotic treatments are effective.

Figure 11 Risk factors for fractures.

4.1 Bone-related risk factors

4.1.1 Previous fracture

Prevalent fracture is (with age) the most important risk factor for subsequent fracture. Hip and non-vertebral-non-hip fractures are easily diagnosed in contrast to vertebral fracture. Thus, assessment of decreased height, back pain and hyperkyphosis are key for indication of X-rays of the spine, or, if available, a vertebral fracture assessment (VFA) VFA using the low-radiation technology of DXA. In a study of postmenopausal women presenting with a non-vertebral fracture, one out of four had a prevalent vertebral fracture on VFA that was

not recognised previously. This situation of ignored vertebral fractures is an issue in RA, and in patients receiving long-term GCs.

Thus, use of VFA should be encouraged in patients at high risk of having vertebral fractures.

4.1.2 BMD measurements

The limitation of a whole population screening with DXA is its low sensitivity. Moreover, the use of clinical risk factors to trigger a BMD test improves the estimation of fracture risk given by the BMD alone and can guide clinicians and patients in understanding the risk of an osteoporosis-related fracture; it can also inform decisions aimed at mitigating these risks (e.g., initiation of bisphosphonates treatment)

4.1.3 FRAX tool

Several clinical factors are associated with a fracture risk that is greater than what can be accounted for by bone mineral density alone. Fracture risk assessment, therefore, should employ specific risk factors in addition to bone mineral density. On the basis of a series of meta-analyses undertaken to identify clinical risk factors for osteoporosis, the Fracture Risk Assessment Tool (FRAX) was developed and released in 2008. This tool integrates the weight of relevant (and easily assessable) risk factors, with or without BMD, to calculate the individual 10-year probability of major osteoporotic fractures (clinical spine, hip, forearm and humerus) (Kanis *et al*, 2011*). The tool has been constructed using data from nine population-based cohorts (60 000 women and men) around the world, and the mortality data of each country. The variables are:

- gender
- age
- body mass index
- a previous fragility fracture
- parental history of hip fracture
- current tobacco smoking
- ever long-term use of oral GCs
- RA
- other causes of secondary osteoporosis
- alcohol consumption of 3 or more units daily.

Based on the FRAX calculation, the 10-year absolute risk of an individual is calculated. The next question is: when is this risk unacceptably high? Most guidelines consider that the intervention threshold varies by age, from roughly 10% at the age of 50–60 years to 30% at the age of 80–90 years for the risk of a major osteoporotic fracture. This may seem counterintuitive, but is in accordance with the spontaneous increase in

fracture risk with age. USA guidelines use a fixed threshold of $\geq 20\%$ for major osteoporotic fractures based on cost effectiveness criteria.

For example, an 80-year-old woman weighing 50 kg and 165 cm tall with a previous fracture, a mother with a hip fracture, and being prescribed prednisone 15 mg/day for RA, is at particularly high risk for fracture: her 10-year risk of hip fracture is 26% and 28% for a major fracture according to the FRAX algorithm. In contrast, a 55-year-old woman weighing 70 kg and 165 cm tall, without any of the above clinical bone-related risks, is at very low risk of having fractures: her 10-year risk of hip fracture is 0.24% and 2.2% for a major fracture according to the FRAX algorithm. The FRAX-generated risk can be modified in the light of daily steroid dose.

There are several important limitations that need to be considered when FRAX is used as a calculation tool. Other important risk factors for fractures are not included in this calculation tool. These include the serum level of 25-hydroxyvitamin D, physical activity level, risk of falls, number of fractures, cumulative dose and duration of glucocorticoids. Therefore, the calculated risk may be less than the actual risk, which has been shown in several cohort studies. In addition, FRAX does not take into account bone mineral density at the spine or the substantially higher risk of spine fracture among those with a history of vertebral fractures.

4.1.4 Evaluation of bone quality

Given the limitations of the measurement of areal BMD several non-invasive imaging techniques have been developed to overcome this difficulty. They are based on the assessment of bone microarchitecture. While some techniques, e.g., peripheral high resolution peripheral quantitative tomography (HRpQCT), are still research tools, another - the trabecular bone score (TBS) starts to be employed in some areas. This is a texture analysis based on the differences in the levels of grey visible on the image of the lumbar spine by DXA. Recently, this technique has been proposed to adjust the FRAX score.

4.1.5 Synthesis

The optimal strategy must be based on the assessment of risk factors and the prediction of the risk of fracture in the subsequent years (and not a theoretical lifetime risk). This is easy in some situations (elderly woman with very low BMD (T score of -3 or below), and/or prevalent hip or vertebral fracture. Otherwise, the FRAX tool (www.shef.ac.uk/FRAX) can be used. Of note, the calculation on this website must be country-specific, given the variations in epidemiology of fracture across countries.

4.1.5 Bone turnover markers

Markers of bone turnover have been extensively used in clinical research. They reflect the dynamic process of bone metabolism. In untreated subjects, increased markers of bone resorption have been associated with the risk of vertebral and non-vertebral fractures, independently of BMD in population studies. However, their use

in predicting fracture risk in specific patients has not been defined clearly as a result of wide intra-individual variation. Potential uses of bone markers include early prediction of changes in BMD during treatment, monitoring of drug efficacy, and selection of patients for treatment. They have no use in the diagnosis of osteoporosis or prediction of BMD and fracture prediction, but they can have a role in monitoring adherence to therapy.

4.2 Fall-related risk factors

For any given bone density, the risk of fracture is greater in the elderly. The increased frequency of falling, the type of fall that occurs among the elderly, and the loss of protective soft tissue may all explain the larger contribution of age and the less important role of bone mass in the elderly. Among postmenopausal women in the United States, the frequency of at least one annual fall rises from about one in five at 60 to 64 years of age to one in three at 80 to 84 years of age. Propensity for falling has been assessed in several studies with parameters such as gait speed, inability to rise from a chair without using one's arms, and of course, visual impairment. These parameters are associated with a risk of falling. The increase in falling is nevertheless not sufficient to account for the increasing incidence of fractures because only 5% to 6% of falls result in a fracture (1% of hip fractures and 4%–5% for other fractures). Fracture risk is also related to the seriousness of the trauma on the femur and the direction of the fall. Indeed, the risk of hip fracture is 13 times higher when the impact is delivered directly over the hip. A great amount of force can be dissipated by the thickness of soft tissue over the femur, and patients with low fat mass may be at higher risk of hip fracture.

Evaluation of the risk of falls can be time consuming (balance and muscle force tests) but can also be easy: a history of falls and ability to rise from a chair without using one's arms can be assessed in daily practice. A strong risk factor for falls is a fall in the past 6 months. Importantly, this assessment is relevant as it has been shown in a meta-analysis that specific fall-related interventions result in a reduced fracture risk (table 4).

Sarcopenia is considered as a reduction in muscle mass and muscle strength due to age. It is mainly a condition of the elderly, but may also be encountered in people with cachexia, cancer, inflammatory diseases and malnutrition. Muscle weakness is one of the causes of falls, so it also determines part of the risk of fracture. Bone and muscle are also tightly associated, because they both develop from the somatic mesoderm and changes in muscle and bone mass are generally correlated. Bone and muscle mass are influenced by the genetic background, sex steroids, various growth factors and mechanical forces. Both muscle and bone mass may be synchronized, under predominantly muscle influence. The communication between the two tissues probably relies on various paracrine/endocrine factors such as the myokines, which secretion may be triggered by mechanical signals.

Table 4 Risk factors for falling in the elderly

	General problem	Specific problem
Intrinsic factors	General deterioration associated with ageing	Poor postural control, defective proprioception, reduced walking speed, weakness of lower limbs, slow reaction time, various comorbidities
	Balance, gait or mobility problems	Joint disease, cerebrovascular disease, peripheral neuropathy, Parkinson's disease, alcohol, vitamin D deficiency
	Visual impairment	Impaired visual acuity, cataracts, glaucoma, retinal degeneration
	Impaired cognition or depression	Alzheimer's disease, cerebrovascular disease
	Blackouts	Hypoglycaemia, postural hypotension, cardiac arrhythmia, transient ischaemic attack, acute onset cerebrovascular accident, epilepsy, drop attacks
Extrinsic factors	Personal hazards	Inappropriate footwear, clothing
	Multiple drug therapy	Sedatives, hypotensive drugs, glucocorticoids
Environmental factors	Indoor/home hazards	Bad lighting, steep stairs and lack of grab rails, slippery floors and loose rugs, tripping over pets and toys, etc.
	Outdoor hazards	Uneven surfaces, lack of safety equipment, bad weather, traffic and public transportation

SUMMARY POINTS

- In elderly postmenopausal women, bone resorption and subsequent bone formation are upregulated.
- Low bone mineral density is an important predictor of future fractures, but only a surrogate for bone strength; bone strength is an umbrella term that covers the structural properties of bone, its material properties and bone turnover.
- New data have provided insight into the role of osteocytes in mechanotransduction, and the role of the Wnt signalling pathway in the formation of new bone.
- In patients with rheumatoid arthritis, the RANKL/OPG ratio is upregulated and is related to both local and generalised bone loss.
- Inhibition of bone formation plays a central role in the pathogenesis of glucocorticoid-induced osteoporosis.
- Case finding of postmenopausal women at highest risk for fractures includes the identification of clinical bone and fall-related risk factors and bone densitometry.
- The FRAX algorithm for case finding is available on the web for calculating the 10-year fracture risk in women and men.
- Recognising vertebral fractures remains a challenge, as two out of three do not present with the clinical signs and symptoms of an acute fracture, and requires special attention for other clinical signs and meticulous observation of vertebral shapes on X-rays or DXA-generated lateral images of the spine.

IN-DEPTH DISCUSSION I

Glucocorticoid-Induced Osteoporosis (GIO)

Introduction

Glucocorticoid (GC) therapy has a strong anti-inflammatory effect, but its long-term use may also lead to side effects: osteoporosis and associated fractures, particularly of the spine and hip, are among the most devastating (1,2). Glucocorticoid-induced osteoporosis (GIO) is the most common cause of secondary osteoporosis and the leading iatrogenic cause of the disease. It is estimated that 0.5% of the adult population chronically uses GC, and that this percentage may even be higher in the elderly, up to 4.6% among postmenopausal women (3). The main causes of GCs use are inflammatory rheumatic disorders (rheumatoid arthritis, polymyalgia rheumatica...) and lung disorders (asthma and chronic obstructive lung diseases). A key point is that the underlying inflammation for which GCs are used has also a role in bone fragility, as there is a strong relationship between inflammatory cells and bone cells. This is one of the determinants of the rapid bone loss occurring at the initiation of GCs.

Pathogenesis

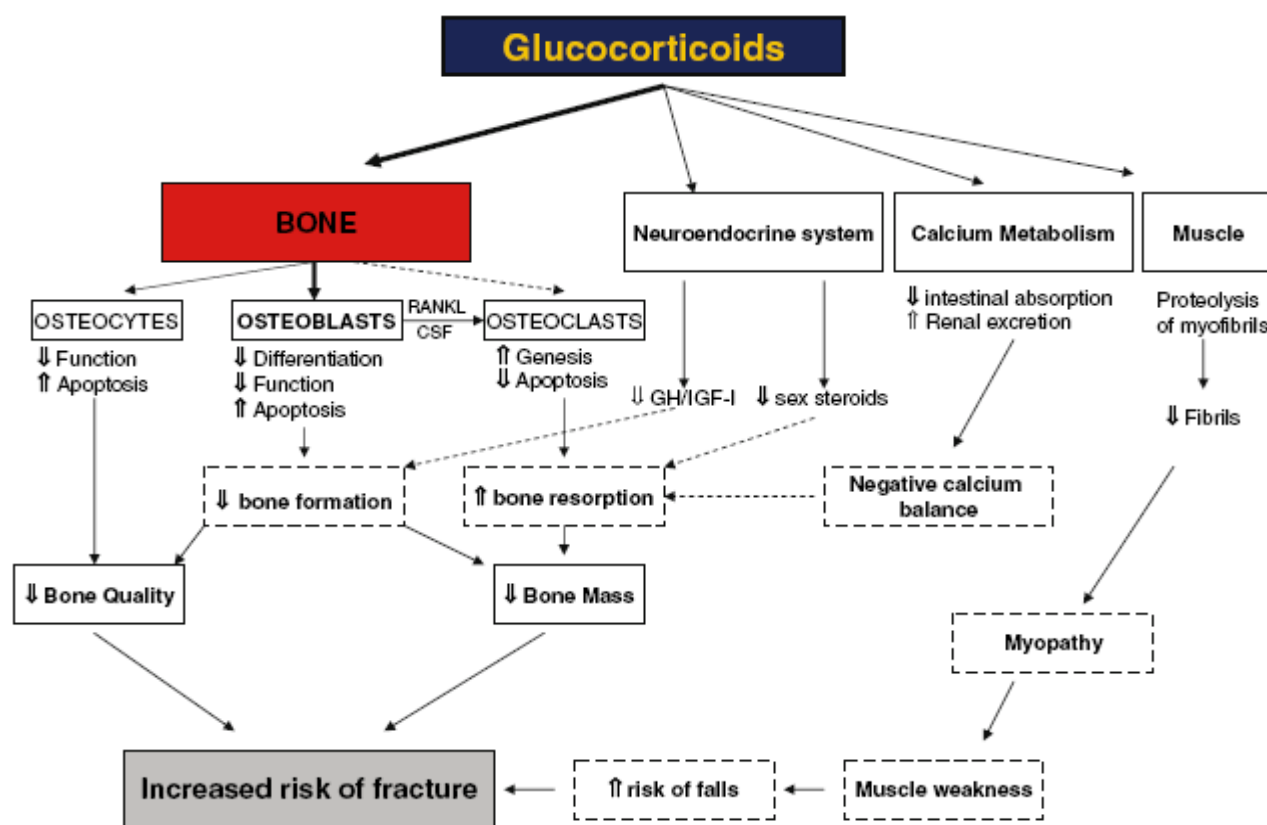

The bone fragility in GIOP is characterized by 2 key points: the early and rapid bone loss at the introduction of the GCs, and the discrepancy between an often unaltered bone mineral density and the risk of fracture. These 2 points can be explained by the pathogenesis of GIOP. While in healthy women bone formation and bone resorption are coupled under normal physiological circumstances, and are upregulated in postmenopausal osteoporotic women, these processes are uncoupled during GC-treatment (4). Bone formation is inhibited during the use of GC, while bone resorption is elevated or unchanged. However, interpretation of bone remodelling in patients receiving GCs should consider the bone effect of inflammation related to the underlying disease. Therefore, studies on the effect of GC on healthy volunteers, without the effects of the underlying disease, are of great interest. In a study in young healthy male volunteers, prednisone (10 mg per day for 1 week), decreased serum osteocalcin (a marker of bone formation) by 22% (6), while no changes were found in pyridinoline and deoxypyridinoline (both markers of bone resorption). A profound decrease of markers of bone formation has been shown also in healthy postmenopausal women receiving 5mg per day of prednisone. GCs have direct and indirect effects on bone turnover (Figure 1). The most consistent skeletal effects of glucocorticoids are to inhibit osteocytes and osteoblasts function. Several mechanisms are involved: decrease in the production of bone anabolic factors (IGF1, TGF β), interference with the Wnt signalling pathway with upregulation of Wnt inhibitors such as Dickkopf-1 and sclerostin. In addition, GCs stimulate apoptosis of osteoblasts and osteocytes: the increased apoptosis of osteoblasts has a negative effect on bone formation, while the increased apoptosis of osteocytes has a strong negative effect on bone strength. GCs have also the potency to stimulate the differentiation of mesenchymal stem cells into the adipocyte pathway, at the expense of differentiation into osteoblasts. Effects on osteoclasts are controversial; GCs upregulate the ratio RANKL/OPG and may increase osteoclastogenesis, as a direct consequence of suppressed osteoblast

differentiation (4). Importantly, glucocorticoid-induced increased collagenolysis by osteoclasts allows continued contact of osteoclasts with mineral, thereby maintaining resorption uninterrupted. As a result, glucocorticoids change the osteoclastic resorption mode from intermittent to continuous, leading to trench-like excavations, rather than the usual round-shaped resorption pits (6). This phenomenon - by impairing quickly the mechanical properties of bone - may explain the rapid rise in fracture risk, despite limited reduction in BMD.

GCs have also a direct catabolic effect on muscle mass and muscle force. The incidence of muscle weakness and myopathy can reach as high as 50% of patients receiving long term GCs and may increase the risk of falls and fractures. Schematically, the complex pathogenesis of GIOP is shown in figure 1.

There is a huge variability of side effects of GCs among individuals including for bone loss, for largely unknown reasons. Attention has been paid to the 11β -hydroxysteroid dehydrogenase (11β -HSD) system, which is a prereceptor modulator of GC action. This system catalyses the interconversion of active/inactive cortisone, and the 11β -HSD1 enzyme amplifies GC signalling in osteoblasts. Interestingly, 11β -HSD, widely expressed in GCs target tissues including bone can be modulated and amplified by pro inflammatory cytokines (7), age, and GC administration itself, suggesting that the mechanism could be a key regulator of GCs effects on bone. Individual GC sensitivity can also be regulated by polymorphisms in the GC receptor gene

Figure 1. Pathogenesis of GIOP, Canalis et al, Osteoporosis Int. 2007 (5).

Epidemiology and risk factors

The use of GCs has not only a devastating effect on bone mass and bone strength, but also on fracture risk. Fracture risk is increased within the first 3–6 months after starting glucocorticoids, the greatest risk being for vertebral fracture. Following withdrawal of glucocorticoid therapy, fracture risk decreases, with the improvement in BMD. A residual risk remains, related to the underlying disorder for which GCs are prescribed. Several large case–control studies have shown strong associations between exposure to glucocorticoids and the risk of fractures. In the largest study, that included >250.000 GC-users and the same number of age-matched controls, the risk of hip and vertebral fractures was elevated in patients treated with high dosages of prednisone, but also in those treated with daily dosages between 2,5 and 7,5 mg per day (8). The risk of hip fractures was doubled, and of vertebral fractures was increased by 2 to 4. GIO mostly affects trabecular bone of vertebrae. In postmenopausal women receiving long term GCs, systematic spine radiographs showed the presence of asymptomatic vertebral fractures in 37% of patients (9). Assessment of vertebral fractures is highly recommended in the management of patients with GCs, considering that these fractures can be asymptomatic because of analgesic effect of GCs.

There is some evidence that high doses of inhaled glucocorticoids may be associated with reduced BMD and a small increase in fracture risk; increased fracture risk has also been reported with intermittent oral glucocorticoid therapy.

Many risk factors are associated with GIO: age, menopause, previous fracture, low body mass index, high GC dose (high current or cumulative dose), underlying disease (rheumatoid arthritis).

Risk fracture assessment in patients receiving glucocorticoid therapy

Fracture risk assessment is recommended for patients starting and/or receiving GCs for at least 3 months. It includes:

- Clinical history with details of co-morbidities, GC use (previous or ongoing, dose, duration and route of administration), fracture history (type and trauma), alcohol intake, smoking, family history of osteoporosis and hip fracture, risk of fall.
- GCs are one of the risk factors in FRAX. However, FRAX underestimates the effect of GCs on the fracture risk because GC use is a yes-or-no question which does not consider the dose and the duration of GCs. The WHO proposed an upward adjustment of risk for patients on 7.5 mg per day of prednisone or more.
- Measurement of the patient's height; height loss suggests the possibility of prevalent vertebral fractures

- There is a mismatch between BMD data and fracture data in patients receiving GCs because of the disparity related to the alteration of bone quality. At similar levels of BMD post-menopausal women taking GCs have considerably higher risks of fracture than controls non-users of GCs (10). Measurement of BMD by DXA at the spine and hip are insufficient to predict the risk of fracture (10). However, the incidence of fractures is higher in patients having $T < -2.5$ and beginning GCs and in patients starting the treatment without osteoporosis. A practical approach is to recommend a BMD measurement in GCs users (optimally at the initiation of treatment) and to consider that patients with $T \leq -2.5$ as those who should receive the highest priority for treatment. But beyond the BMD, a more comprehensive approach of the risk is necessary and clinical judgment remains needed. Lateral imaging DXA with vertebral fracture assessment (VFA) for the detection of existing vertebral fractures; if this is not available, lateral X-rays of the thoracic and lumbar spine should be considered in patients with back pain and/or height loss.
- Laboratory testing should be performed to exclude causes of secondary osteoporosis other than GC use including assessment of vitamin D status and renal function.
- Since bone turnover after long-term glucocorticoid therapy is low, tests bone remodelling markers are not helpful in GIO.

Strategies of prevention and treatments of GIO

1. General measures

General measures are recommended for all patients starting or receiving GCs for at least 3 months. Life-style measures are important, which include adequate levels of dietary proteins and calcium intake and vitamin D supplementation, maintenance of a normal body weight. Tobacco use and alcohol abuse should be avoided. The risk of falling should be assessed in particular in elderly patients, patients with painful joints of the lower limbs, patients with massive doses of GCs... Physical activity or mobilization should be considered, adapted to the underlying condition. Use of alternative immunosuppressive agents enable to reduce the dose of GCs should be considered and alternative routes of administration (e.g. topical, inhaled) or formulations should be preferred. Because glucocorticoid therapy is associated with reduced intestinal and renal calcium absorption and increased urinary calcium excretion, increasing calcium intake seems a logical approach. It is suggested that the total daily intake of calcium should be above 1000 mg. The Cochrane review of these RCTs concluded that sufficient calcium and vitamin D supplements are a prerequisite in patients using GC. Adequate vitamin D levels are not only important for adequate bone mineralization, but also for an optimal neuro-muscular function, as muscles have also vitamin D receptors and low vitamin D levels are associated with an increased the risk of fall. Based on elevated levels of PTH and markers of bone resorption in patients with serum 25 OHD levels up to 50 nmol/L, the cut-off value of adequate serum vitamin D levels is nowadays considered at least 50 nmol/L, but probably should achieve 75 nmol/L in the context of optimal muscle function.

2. Pharmacological interventions

Although several interventions have been evaluated in the management of GIO, the strength of evidence for their efficacy is weaker than that for postmenopausal osteoporosis, since fracture reduction has not been a primary end-point of any study. Bisphosphonates (alendronate, risedronate, zoledronic acid) are considered the first-line treatment option for most glucocorticoid-treated patients at increased risk of fractures (11, 12, 13). However, the anti-resorptive mechanism of bisphosphonates does not address the major pathophysiological mechanisms of impaired bone formation during chronic glucocorticoid treatment. PTH, administered intermittently has effects on bone formation opposite to those of glucocorticoids and therefore is conceptually a more attractive approach. In a 18-month RCT, Saag et al compared the anabolic agent teriparatide with alendronate in 428 women and men with osteoporosis, who received GCs (>5mg per day) for at least three months (14). The increase of lumbar spine BMD was significantly higher in teriparatide group than in alendronate group (7,2% versus 3,4%), with a significant decrease of new vertebral fractures in the teriparatide group (0,6% vs 6.1% in the alendronate group, $p=0.004$). Results were confirmed at 36 months (15). There is no evidence of a positive effect of bisphosphonates and teriparatide on the risk of non-vertebral fractures.

3. Indications of anti-osteoporotic treatments

Because rapid bone loss and increased fracture risk occur soon after the initiation of GCs, anti-osteoporotic treatments should be started at the onset of GCs therapy in individuals at high risk of fracture. Several recommendations elaborated by various international societies, based on the presence of low trauma fracture, age, daily dose of GCs, and the T score have been proposed. The American College of Rheumatology (ACR) last updated their guidelines in 2017 using an approach based on the FRAX calculation of the fracture risk (16). The European Calcified Tissue Society (ECTS), in collaboration with the International Osteoporosis Foundation (IOF), has also published GIOP guidelines (17)

In postmenopausal women and men aged above 50 years, anti-osteoporotic treatments are indicated in case of (one condition required): previous low trauma fracture, age ≥ 70 years, high doses of GCs (≥ 7.5 mg prednisone equivalent) and low T score (17).

Premenopausal women and men aged 50 years or less have a lower risk of fractures than older individuals. Data on the effect of pharmacological treatments are sparse. Anti-osteoporotic treatments can be recommended in patients with a previous low trauma fracture. In the other situations, treatment decisions are based on clinical judgment (17). Bisphosphonates should be used cautiously in premenopausal women, as they cross the placenta and women of childbearing potential should be under appropriate contraception before introducing bisphosphonates

4. Insufficiency of management

Although both effective drugs and several guidelines for prevention of GIOP are available, epidemiological data have shown that adequate prophylaxis is improving over the years. Yet, these drugs are prescribed only in roughly 50% of the GC-treated patients (18). Although an increase in adherence of patients to therapy, which is prescribed for prevention (of fractures) is difficult to achieve, amongst others because anti-osteoporotic drugs are prescribed for prevention (of fractures), this certainly is a challenge for the coming years.

IN-DEPTH DISCUSSION II

Osteoporosis in inflammatory joint disorders

Introduction

Bone tissue is a target of inflammatory diseases, and bone loss is a complication of persistent inflammation. This chapter focuses on two inflammatory joint diseases: rheumatoid arthritis (RA) and ankylosing spondylitis (AS). Osteoporosis is common in these two inflammatory joint diseases due to the relationships between inflammation, immune system and bone remodelling (1).

Rheumatoid arthritis

Bone complications are the main extra-articular complications of the disease and are described as three different forms: periarticular bone loss (adjacent to the swelling joints), bone erosions, and systemic osteoporosis.

Fracture risk and risk factors

RA is one of the items of the FRAX® to estimate the 10-year risk of fracture in the general population, and the item is stated separately to corticosteroid and other secondary osteoporosis. RA doubles the risk of hip and vertebral fractures, regardless of the use of corticosteroids (2). Vertebral fractures may not come to clinical attention in RA because of analgesics use for painful joints (3). Thus, vertebral fracture assessment (VFA technology on dual X-ray absorptiometry (DXA) devices) should be used in these patients at the time of BMD measurement. Patients with RA are at high risk of osteoporosis and fractures because they have several well-known risk factors: menopause, low BMI, reduced physical activity, and corticosteroid therapy, but inflammatory disease activity may be the most important factor associated with bone loss in RA. Several studies have shown that disability is a risk factor for fractures in RA. The link between orthopaedic surgery and the incidence of fractures in RA has been reported and fall rates in RA patients are higher than in the general population (4, 5). Fall rates in RA patients is higher than in the general population. Falling risk is related to stiff and painful joints, muscle weakness, low postural stability, and reduced physical performance. Accumulated disease activity and inflammation negatively affect lean mass, and sarcopenia/rheumatoid cachexia is a component of the muscle weakness (6). Progressive resistance training programs can be used to prevent part of muscle weakness in RA.

Bone density in RA

Osteoporosis is common in RA, and is obviously one of the determinants of the risk of fractures (7). However, the relationship between decreased BMD and fracture is less clear in RA than in post-menopausal osteoporosis. In RA patients followed prospectively in the 1990s, including patients without corticosteroids, a decrease in spine and hip BMD was reported suggesting that disease activity is the main determinant of BMD decrease, and that suppression of disease activity may prevent the bone loss. Management of RA has changed

over the last years and the objective of the treatments is now the remission of the disease; prevention of bone loss is therefore expected. Observational studies showed that a better control of inflammation corrects the uncoupling of bone resorption (increase in bone resorption and decrease in bone formation) that is observed in RA (8). TNF α blockers are able to arrest BMD loss, supporting a parallel between inflammation control and bone loss arrest in RA (9,10). This arrest of bone loss on TNF blockers is likely to be mediated by a return to a normal bone coupling (11).

Treatment of osteoporosis in RA

As most patients with RA are receiving glucocorticoids, guidelines on the prevention and treatment of glucocorticoid-induced osteoporosis must be applied, including by using bisphosphonates or teriparatide as appropriate. Underlying conditions as menopausal status, level of physical activity, and risk of falls must be assessed for an appropriate prevention of fractures in RA. The different families of biologic therapies can prevent structural damage and also have beneficial effects on bone loss by curbing inflammation and restoring normal bone turnover (12). However, there is no evidence of an antifracture efficacy of these treatments (13). Suppression of inflammation is also the objective for optimal prevention of osteoporosis. Denosumab, that inhibits RANK-L, has been used in patients with RA in several studies. There was no clinical benefit on arthritis, but a reduction of bone damage, a sustained decrease in markers of bone turnover and a 2–4% increase in BMD over 1 year (14).

Ankylosing spondylitis (AS)

Although bone formation is to be the cornerstone of the disease, AS is also associated with a systemic osteoporosis. This osteoporosis cannot be related to the underlying characteristics of the patients like in RA, as AS is typically a disease of young men and glucocorticoids are not used in AS. Patients with AS have an increased risk of osteoporosis which can be observed in the early stages of the disease suggesting that it is not only related to spinal immobilisation observed in advanced cases (15).

Fracture risk in AS

Patients with AS have an increased risk of vertebral fracture, but not of non-vertebral fractures, except in one study (16-17). Vertebral fractures are less frequent than in RA but may lead to major neurological complications, a specific observation in AS. The prevalence of vertebral fractures in AS is very different among studies, and this illustrates the large heterogeneity of the studied populations and the difficulty of diagnosis of these fractures in AS. Spine fractures in AS can be transdiscal, i.e., between two vertebral bodies, in ankylosed spine; although they can occur after a low trauma and reflect bone fragility related to spine stiffness and decreased BMD, they should not be counted among vertebral bodies fractures. Erosions can occur in AS, at the anterior corners of the vertebral bodies, related to the adjacent enthesitis, leading to vertebral deformities,

wedging of vertebrae, and hyperkyphosis in some patients. These deformities, leading to wedging of the vertebral bodies, should not be considered for the estimation of osteoporotic VF prevalence. Using visual or morphometric definitions, prevalence of VFs is 10–30% (18-20). In a retrospective population-based study on clinical fractures, the odds ratio (OR) for clinical vertebral fractures was reported to be 7.7 (4.3–12.6) and even higher in men (18). Patients with vertebral fractures have lower BMD than patients without, and femoral neck is the best discriminant site. However, low BMD is not sufficient for the prediction of fracture in this population. Bone remodelling markers assessment is not indicated for evaluation of fracture risk in SpA.

Risk factors of clinical vertebral fracture in patients with AS are the presence of inflammatory bowel disease (associated with corticosteroid use), subclinical malabsorption, and systemic inflammation. A decreased risk of fracture has been reported in patients with AS taking non-steroidal anti-inflammatory drugs (NSAIDs). Whether the effect is due to a direct bone metabolic effect of NSAIDs or an indirect one through a better physical activity is unknown.

Bone density in AS

Osteoporosis has been reported as an early event in AS. Prevalence of osteoporosis according to bone mineral density (BMD) measurements is 14–27% and 4–14% at the spine and hip, respectively, which is unexpectedly high in these patients aged on average 30-40 years. In a cohort of young patients with early inflammatory back pain suggestive of spondyloarthropathies (disease duration of symptoms 1.6 years), 13% of patients had a low BMD (Z score ≤ -2). The main determinants of low BMD were bone and systemic inflammation as assessed by MRI and biological parameters (23). Presence of bone marrow oedema (BMO) lesions on MRI increases 5-fold the risk of having a low spine BMD and presence of BMO lesions on spine MRI was the single determinant of low hip BMD, suggesting a systemic effect of inflammation. Osteoporosis can occur because of reduced physical activity, decreased spine mobility related to pain, stiffness and ankylosis, and/or subclinical gut involvement. Genetic factors have been suspected, and vitamin D receptor gene may contribute to BMD differences in patients with AS; these polymorphisms are also linked to inflammatory activity. Prospective studies in patients with AS suggest that a decrease in BMD is observed mainly in patients with permanently increased CRP (24-25). In patients receiving anti-TNF therapy, there is an increase in BMD, and a decrease in resorption markers (serum CTX-1). The HLA B27 transgenic rat, a relevant model of AS exhibit decreased bone strength, and increased RANK L/OPG ratio, suggesting the implication of this system in the systemic bone loss (26).

Treatment of osteoporosis in AS

No specific clinical trial has been conducted in this population. In a post-hoc analysis of the ASSERT trial, however, the use of infliximab was associated with restored bone coupling and improved BMD (27). In patients without indication for anti-TNF therapy, current guidelines for treatment of male osteoporosis and

premenopausal women must be applied. In patients with anti TNF therapy and low BMD, it seems logical to assess the benefit given by this treatment before introducing an anti-osteoporotic drug (27-28).

Osteoporosis: Treatment

Elaine Dennison, Christopher Chan, René Rizzoli

A previous version was coauthored by Emmanuel Biver, Bernard Cortet, René Rizzoli

LEARNING OBJECTIVES

- Manage calcium and vitamin D deficiency
- Evaluate the difference between the diagnosis threshold and the therapeutic threshold in osteoporosis
- Critically assess the efficacy of treatments according to their effect on vertebral and/or non vertebral fractures
- Educate patients on persistence and side-effects of treatments

1 General considerations

Provided that the diagnosis of osteoporosis has been properly made and secondary forms of osteoporosis excluded, the treatment of osteoporosis includes non-pharmacological interventions and the use of anti-osteoporotic drugs with proven antifracture efficacy. The general management of osteoporosis includes the elimination of preventable risk factors for osteoporosis and osteoporotic fractures. There are numerous risk factors for osteoporosis and osteoporotic fractures, but only a few can be targeted by interventions (table 1).

Table 1 Preventable risk factors associated with osteoporosis and fragility fractures

Evidence of intervention efficacy	Low evidence of intervention efficacy
<ul style="list-style-type: none"> • Vitamin D insufficiency • Low calcium intake • High risk for falling 	<ul style="list-style-type: none"> • Low body weight or body mass index • Smoking • Alcohol intake

The aim of osteoporosis treatment is the prevention of fragility fractures. A pharmacological intervention is justified when the benefits (decreased fracture risk) outweigh both the side effects and the economic costs of the treatment (i.e., the so-called treatment threshold). Any non-pharmacological intervention for risk factors for osteoporotic fractures (table 1) has negligible costs, might be associated with general health benefits and may be implemented by community interventions (eg, recommending giving up smoking, or increase calcium intake).

2 Non-pharmacological management of osteoporosis

Non-pharmacological interventions are useful for patients with osteoporosis. Also the recommendations discussed below may be applicable for patients with low bone mineral density (BMD) with the aim of avoiding the occurrence of osteoporosis.

2.1 Physical activity

Immobilisation and bed rest quickly lead to muscle weakness and bone loss. For this reason, immobility should be avoided whenever possible. Young individuals practicing weight-bearing sports activities have higher bone mass than controls, particularly at the most stressed skeletal sites, but the effect of physical exercise in postmenopausal women is more controversial as the amount of weight-bearing exercise that is optimal for skeletal health in patients with osteoporosis is unknown. Despite these uncertainties, exercise is an integral component of osteoporosis management because it helps to increase muscle strength and to improve confidence and coordination, thus preventing falls. Mechanical loading also induces new bone formation by preventing the expression of sclerostin, a negative regulator of bone formation produced by osteocytes. Thus, despite a low level of evidence, exercise such as walking, weight bearing, aerobics and resistance exercises

were reported to have an effect on BMD and muscle strength and should be encouraged in osteoporosis management (Howe *et al*, 2011).

2.2 Prevention of falls

The prevention of falls is of crucial importance in the very elderly and the strategies targeted to decrease the most common risk factors for falling (box 1) are recommended. Currently, there is no study showing that it is possible to decrease the incidence of fractures through a fall prevention strategy only. Some interventions for preventing falls in elderly people have been suggested, such as muscle strengthening and balance retraining, home hazard assessment and modification, withdrawal of psychotropic medication, cardiac pacing, and tai chi group exercises. Multifactorial interventions in long-term care populations seem more likely to be beneficial. Frequent fallers and frail individuals must receive the highest priority for osteoporosis treatment (Neyens *et al*, 2011).

Box 1 Risk factors associated with falls

- Age
- Impaired mobility (lower limb osteoarthritis, neuromuscular disorders, etc)
- Impaired vision
- Cardiovascular diseases (arrhythmias)
- History of falls
- Medication
- Cognitive impairment
- Environment (slippery surfaces, inappropriate shoes, carpets, insufficient lighting, etc)

In institutionalised very elderly patients at extremely high risk of falling, hip protectors were shown to reduce the risk of hip fracture, but patient acceptance is rather low and the results inconsistent in patients living in the community (Parker *et al*, 2006; Oliver *et al*, 2007).

2.3 Protein intake

The typical Western diet includes a lot of protein. However, among the very elderly, a diet consisting almost exclusively of carbohydrates is quite common and this is associated with inadequate function of the musculoskeletal system. Correction of poor protein intake can limit the age-related alteration of the growth hormone–IGF-1 axis and improve BMD as well as muscle mass and strength (Rizzoli and Bonjour, 2004; Rizzoli *et al*, 2014*). Increased protein intake has also been shown in patients with a recent hip fracture to improve the subsequent clinical course and reduce the duration of hospital stay.

2.4 Fracture liaison services

As the risk of fracture increases after the first fracture and osteoporosis often goes undiagnosed and untreated in this situation, fracture liaison services may implement clinical pathways in liaison with orthopaedic units for the diagnosis and treatment of osteoporosis in patients with fragility fractures. Such strategies were reported to be cost-effective and are currently being established in many countries (McLellan *et al*, 2011).

3 Calcium and vitamin D

The main nutrients relevant for bone health are calcium, protein and vitamin D. Inadequate intake of these nutrients may occur as a consequence of diseases (eg, intestinal malabsorption), but is also quite common in the elderly. Calcium and vitamin D supplementation has a beneficial effect on bone health and fracture risk, and may be given to prevent and treat osteoporosis, particularly in elderly and institutionalised patients, patients treated for osteoporosis using antiresorptive or anabolic agents, and patients treated with glucocorticoids. However, irrespective of whether or not these nutrients are necessary, they are not sufficient for patients with a high fracture risk.

3.1 Calcium intake

Calcium intake is found to be weakly related to BMD or BMD changes, and in two meta-analyses it was found to be associated with a modest reduction in fracture risk (better effect with high doses of calcium of 1200 mg or more). It was speculated that positive results on bone turnover, bone mass and fracture risk can be expected from using calcium supplements only in patients with inadequate calcium intake (Shea *et al*, 2004; Boonen *et al*, 2007; Nieves and Lindsay, 2007; Tang *et al*, 2007). The recommended amounts of dietary calcium intake are of 800 to 1200 mg/day in adults older than 50. Many dietary recommendations include the consumption of 3 servings of dairy products per day (for example, 1 glass of milk, 1 portion of cheese, 1 yogurt)—an amount that provides most of the Recommended Daily Intake of calcium for the general population. It appears reasonable to use calcium supplements when dietary calcium intake cannot be increased above 800 mg/day. Calcium supplement dose has been inconclusively debated for a long time. The issue is complicated by the observation that the optimal dose of calcium supplements may depend on vitamin D supplementation (see below). It should also be noted that there are fundamental differences between calcium supplied by the diet and that from calcium supplements (table 2), and these should be taken into account for the management of osteoporosis. It is also worth mentioning that all agents registered for osteoporosis treatment have been tested in patients given calcium and vitamin D supplements.

It is currently debated whether the use of calcium supplements may increase the risk of cardiovascular events, in particular the risk of myocardial infarction. Recent additional data suggest that there is no convincing evidence for an increased cardio-vascular risk at the recommended doses of calcium intakes (Harvey *et al*,

2016). Therefore, it appears reasonable to encourage patients to obtain their calcium needs from food and drink and to use calcium supplements only if a calcium intake of at least 1 g per day is not supplied by their diet.

Table 2 Consequences of increasing calcium intake from 400 mg/day to 1400 mg/day with diet (eg, 800 mL of milk-derived products) or with calcium supplements (eg, one tablet of 1 g calcium carbonate)

Increase calcium intake supplied by the diet	Increase calcium intake with calcium supplements
<ul style="list-style-type: none"> • Slow (mainly active) intestinal absorption • Fraction absorbed proportional to 1,25(OH)₂ vitamin D levels • Associated with excess calcium in the large intestine lumen • Decreased absorption by oxalates • Decreased risk of renal calculi • Provide other nutrients (proteins) 	<ul style="list-style-type: none"> • Fast intestinal absorption (mainly diffusion) • Transient hypocalcaemia, suppression of parathyroid hormone secretion and of bone reabsorption • Transient hypercalciuria • Increased risk of renal calculi

3.2 Vitamin D

There are two chemically distinct forms of plain vitamin D, the native compound: vitamin D3 (cholecalciferol) and vitamin D2 (ergocalciferol), obtained through ultraviolet B (UVB) radiation of the skin (vitamin D3) or through the diet (vitamin D2 or D3). Food and/or supplement intake may provide either vitamin D2 or D3. Sequential hydroxylation in the liver and kidney results in the production of two metabolites: calcidiol (25(OH)D) and calcitriol (1,25(OH)₂D). Vitamin D status must be determined by measuring the serum concentration of the major circulating form of vitamin D, calcidiol (25(OH)D).

Vitamin D deficiency is extremely common in the elderly. The old definition of deficiency and insufficiency was challenged when it was demonstrated that 25(OH)D <50 nmol/L was associated with markers of poor skeletal health (i.e., increased parathyroid hormone (PTH) levels, impaired calcium absorption, lower BMD). These clinical consequences are the basis for switching the definition of vitamin D insufficiency from a biological to a clinical definition—that is, the threshold below which there are consequences for bone (table 3). It was recently recommended that 50 nmol/L (i.e., 20 ng/mL) should be the minimal serum 25(OH)D concentration at the population level and in patients with osteoporosis to ensure optimal bone health. Supplementation with 800–1000 IU/day is recommended for a serum 25(OH)D concentration below 50 nmol/L (i.e., 20 ng/mL), with an intervention threshold that should rise to 75 nmol/L (i.e., 30 ng/mL) in frail elderly patients at elevated risk for falls and fractures (Rizzoli *et al*, 2013*).

On this basis, a large majority of elderly people (40–100% according to several studies) or patients with inflammatory joint diseases, and a high proportion of adults, not taking vitamin D supplements, are vitamin D insufficient (Holick, 2007*). Vitamin D deficiency severely hampers the clinical benefits of antiresorbing therapies (Adami *et al*, 2009*). Vitamin D supplements can also reduce the risk of falling and the risk of fracture through a well-recognised muscle effect. The question of the dose to give is difficult as it depends on the baseline level of serum 25(OH)D and the fat mass of the patient (vitamin D is liposoluble). The optimal dose and dosing is that allowing a circulating level of 25(OH)D of >75 nmol/L. On a daily basis, it is quite difficult to obtain enough vitamin D from dietary sources (even if rich in oily fish). Thus, sensible sun exposure (or UVB irradiation) and the use of supplements (depending on patient exposure to the sun) are needed to fulfil the body's vitamin D requirement. Sunlight is the most important source of vitamin D and stimulates the production of vitamin D₃ in the skin during the summer. During exposure to solar UVB radiation, 7-dehydrocholesterol in the skin is converted to previtamin D₃ and then vitamin D₃. Seasonal variations are observed in serum 25(OH)D, with effects of sunlight exposure that depend on age, skin pigmentation, clothing style and sunscreen use (Lips *et al*, 2014).

Table 3 Vitamin D biological levels

	25(OH) vitamin D	
	ng/mL	nmol/L
Vitamin D deficiency	<10	<25
Vitamin D insufficiency	10–20	25–50
Vitamin D sufficiency	20–30	50–75
Recommended vitamin D level in patients at elevated risk for falls and fractures	30–70	75–175
Possible vitamin D over-dosage	>80	>200

Vitamin D supplements can be given weekly, monthly or at 3-monthly intervals. Except in diseases interfering with vitamin D metabolism (chronic renal or liver failure), there is no justification for using hydroxylated forms of vitamin D (1(OH)D or 25(OH)D or 1,25(OH)₂D) because they expose the patient to an increased risk of hypercalcaemia or nephrolithiasis (particularly for 1,25(OH)₂D). The efficacy of daily administration of vitamin D₂ and D₃ seems to be the same. In case of intermittent administration, vitamin D₃ must be preferred because it induces a longer and more stable 25(OH) vitamin D level than vitamin D₂. To improve vitamin D absorption, it should be taken with a fat-rich diet, such as milk or at the end of the meal. Vitamin D deficiency is so common among elderly people that vitamin D supplements (800 IU/day) can be recommended even in the absence of a measurement of 25(OH)D level, considering that the safety of vitamin D supplements, at doses used in clinical practice, is good. Excess vitamin D, which can cause hypercalcaemia in generally healthy adults, results from a daily intake of >100 000 IU vitamin D, associated with serum 25(OH)D levels of >200

nmol/L, which are far higher than necessary to achieve benefit. Therefore, the use of vitamin D at physiological doses for elderly people without a previous measurement of vitamin D level (i.e., 800–1200 IU/day) is safe.

Two RCT in women showed that high doses of vitamin D (500000 IU of vitamin D per year and 60 000 IU of vitamin D per month, respectively) significantly increase risk of falls (Sanders et al, 2010; Bischoff-Ferrari et al, 2016). Moreover, it was shown that the majority of patients treated with equivalent to 800 IU/day achieve the replete range of above 50 nmol/L 25(OH)D. Therefore, high loading doses of vitamin D are no more recommended. In case of vitamin D insufficiency or deficiency, the recommended daily dose in the average patient (with the target of a serum 25(OH) vitamin D level over the recommended threshold of 50-75 nmol/L) is 800 IU, which can be prescribed in a large variety of compounds from daily to every 3 months administration. If vitamin D deficiency has been documented, the daily dose might be increased to a maximum of 2000 IU/day for one to 3 months before a maintenance dose of 800 IU/day.

3.3 Combining vitamin D with calcium or with bisphosphonates

The addition of calcium is necessary to optimise the clinical efficacy of vitamin D supplementation in terms of reducing fracture risk. The consequences of vitamin D deficiency on PTH secretion are also related to calcium intake. In subjects with a very high calcium intake, moderate vitamin D insufficiency is not associated with secondary hyperparathyroidism. In people with calcium intake as low as 400 mg/day, levels of 25(OH) vitamin D above 100 nmol/L are able to maintain PTH within the normal range, which might be particularly relevant for patients who are unable to increase their dietary calcium and are intolerant of any formulation of calcium supplements (Lips *et al*, 2010).

Vitamin D can be combined with all types of anti-osteoporotic medication. A fixed dose combination of once-weekly alendronate 70 mg and vitamin D3 5600 IU is available for the treatment of postmenopausal osteoporosis.

4 Pharmacological intervention

4.1 Pharmacological treatment threshold

4.1.1 Criteria for treatment threshold identification: BMD, fracture risk factors and FRAX

The aim of osteoporosis treatment is the prevention of fragility fracture. A pharmacological intervention is justified when the benefits (lowering fracture risk) outweigh both the side effects and the economic costs of the treatment. For the latter, treatment threshold may vary according to local health policy (Geusens *et al*, 2008*).

The definition of osteoporosis is based on BMD measurement (Kanis *et al*, 2000). The original World Health Organization (WHO) definition of osteoporosis (a T score of –2.5 or less at any skeletal site) has been recently

adjusted by specifying a reference site (the femoral neck) based on a young normal reference range (WHO, 1994). In clinical practice, the positioning of the area of analysis on the femoral neck is not always easy and the T score of the total hip is an acceptable alternative.

The definition of osteoporosis based on the T score will not change with the use of scores of fracture risk (see below), just as the definition of hypertension has not changed with the use of tools to estimate vascular risk. However, the diagnosis threshold may be different from the therapeutic threshold. Indeed, several factors besides BMD affect the risk of fracture (table 5), so the decision to start an intervention aimed at reducing this risk will be better if it takes all factors into account.

Table 5 Clinical risk factors most widely used for the assessment of fracture probability

Clinical risk factors

- Advanced age
- Female sex
- Low body mass index
- Previous fragility fracture, particularly of the hip, wrist and spine including morphometric vertebral fracture
- Parental history of hip fracture
- Glucocorticoid treatment (>5 mg prednisolone daily or equivalent for 3 months or more)
- Current smoking
- Alcohol intake of 3 or more units daily
- Rheumatoid arthritis
- Other secondary causes of osteoporosis
 - Untreated hypogonadism in men and women; for example, premature menopause, bilateral oophorectomy or orchidectomy, anorexia nervosa, chemotherapy for breast cancer, hypopituitarism
 - Inflammatory bowel disease; for example, Crohn's disease and ulcerative colitis (risk is in part dependent on the use of glucocorticoids, but an independent risk remains after adjustment for glucocorticoid exposure)
 - Prolonged immobility; for example, spinal cord injury, Parkinson's disease, stroke, muscular dystrophy, ankylosing spondylitis
 - Organ transplantation
 - Type I diabetes
 - Thyroid disorders; for example, untreated hyperthyroidism, over-treated hypothyroidism
 - Chronic obstructive pulmonary disease

Prevalent vertebral and hip fragility fractures, or high steroid doses in postmenopausal women, identify categories of extremely high risk patients for whom many European health authorities grant funding for osteoporosis treatments even in the absence of a DXA (dual-energy X-ray absorptiometry) evaluation (Lindsay *et al*, 2001*).

In other patients, the identification of a treatment threshold based on BMD only is more complicated. Fracture risk may vary markedly among different populations for the same BMD value, according to the presence of other risk factors (table 5). Thus, the combination of BMD and clinical risk factors predicts fracture risk better than BMD alone. Fracture risk increases with advancing age, regardless of baseline T score; for example, a T score of -2.5 is associated with a 10-year fracture probability of 6% in a 50-year-old woman, but with a 10-year fracture probability of 26.5% in an 80-year-old (Kanis *et al*, 2001*). A prevalent vertebral fracture increases the risk of incident vertebral fracture by about fivefold in the year following the primary fracture. Also the occurrence of a recent vertebral fracture is associated with a recurrence in the year following the primary fracture in about 20% of cases (Black *et al*, 1999*).

The 10-year probability of a major osteoporotic fracture (vertebral, hip or forearm) can be calculated in treatment-naïve patients (men and women) using femoral neck BMD and clinical risk factors for fracture with a country-specific adaptation of the WHO fracture risk algorithm (FRAX), available online for public use (<http://www.shef.ac.uk/FRAX>). The risk factors included in FRAX are age, sex, weight, height, previous fracture, parent with fractured hip, current smoking, glucocorticoid use, rheumatoid arthritis, secondary osteoporosis, and excess alcohol intake (more than 3 units per day). The risk of fracture can also be calculated without BMD.

FRAX has a number of limitations:

- It is not freely available for automatic application to databases or case report forms.
- It does not take into account the 'dose effect' of some risk factors, such as steroid use (dose and duration) or fractures (number, severity or type). A prior clinical vertebral fracture carries approximately a 2 fold higher risk than other types of prior fracture.
- The fracture risk is not adjusted for the perception of the risk, which may vary individually according to age, life-expectancy and other factors (in particular the risk of falls).
- FRAX does not define intervention thresholds, which depend on country-specific considerations.
- FRAX is not available for all countries. When a country does not have a national reference on FRAX, it seems reasonable to choose the reference of a neighbouring country.
- By using femoral neck BMD, FRAX does not allow the taking into account of spine–hip discordances in T score in patients who have a lumbar spine T score lower than their femoral neck T score.
- FRAX does not consider prior treatment

In light of these points, care providers might tailor treatment thresholds individually. Despite the aforementioned limitations, FRAX is likely to become, in many countries, the most popular instrument for identifying patients to be treated and or entitled to drug reimbursement.

4.1.2 Clinical guidelines for treatment threshold for osteoporosis

In the absence of a universally accepted policy for population screening in Europe to identify patients with osteoporosis or those with high risk of fracture, patients are identified using a case-finding strategy based on previous fragility fracture or the presence of significant risk factors.

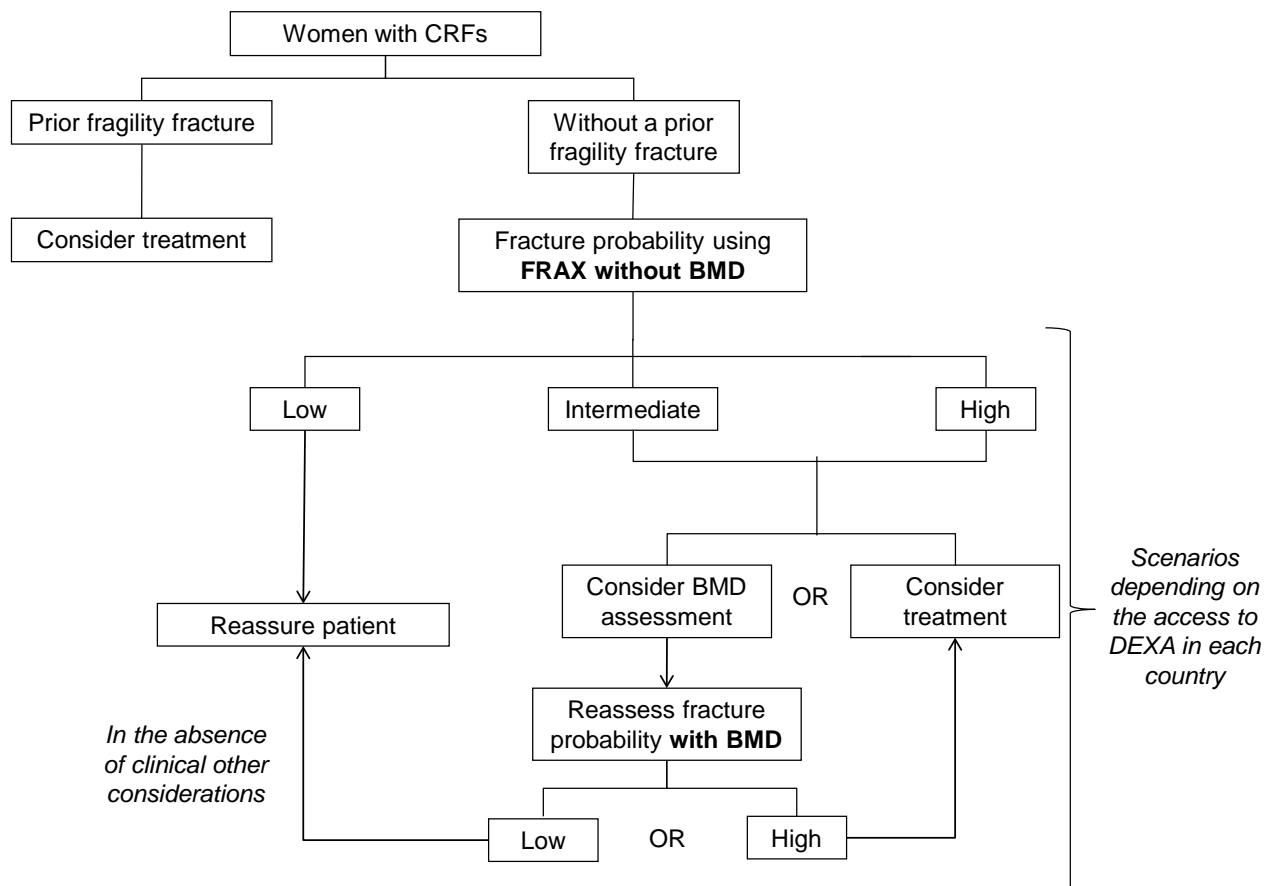

European guidelines for the management of osteoporosis in postmenopausal women were revised in 2012, based on the finding of a previous fragility fracture or the presence of significant clinical risk factors and the use of FRAX (Kanis *et al*, 2013).

The fracture probability at which to intervene, in terms of assessment threshold for BMD testing and intervention threshold for treatment, differs for individual countries according to health economic perspectives and other factors. It is not possible to propose a universal decision threshold for FRAX valid in all countries because the threshold is dependent particularly on each country's healthcare system. In other words, an unacceptable level in one country would be acceptable in another. As an example, in France, in patients without prevalent fractures with a T score greater than -3 , the treatment decision depends on the FRAX probability, and the thresholds for treatment vary with age, as reported in figure 1B (Briot *et al*, 2012). It should be noted that the value of a metatarsal or rib fracture is very different from that of a vertebral or hip fracture. Therefore, no general algorithm can be proposed for use in all countries.

The current treatment guidelines of the US National Osteoporosis Foundation (2014) recommend pharmacological therapy for postmenopausal women and men aged 50 years and older, after appropriate evaluation, presenting with:

- a hip or vertebral (clinical or morphometric) fracture
- a T score of -2.5 or less at the femoral neck, total hip or spine by DXA
- a low bone mass (T score between -1.0 and -2.5 at the femoral neck, total hip or spine by DXA) and a 10-year probability of a hip fracture of 3% or more or a 10-year probability of a major osteoporosis-related fracture of 20% or more based on the US-adapted WHO algorithm. Some situations associated with negative effects on the skeleton require specific approaches, in particular to prevent bone loss and fracture risk associated with aromatase inhibitors (Rizzoli *et al*, 2012a), or in geriatric populations (Rizzoli *et al*, 2014*).

Figure 1 (A) Proposed management algorithm for the assessment of individuals at risk of fracture, to be modified in each country according to local dual-energy X-ray absorptiometry (DXA) access and reimbursement issues. (B) Intervention threshold for osteoporosis treatment described in French recommendations. BMD, bone mineral density; CRF, clinical risk factor. 4.2 Pharmacological treatment options

The drugs registered in Europe for the treatment of postmenopausal osteoporosis are listed in table 6.

Table 6 Pharmacological agents licensed in Europe for the treatment of postmenopausal osteoporosis

Drug		Bone targets and mechanism of action	Dose in osteoporosis treatment	Effect on fracture risk reduction demonstrated in clinical trials			Side/off-target effects and adverse effects
				Vertebral	Non-vertebral	Hip	
Bisphosphonates	Alendronate	Inhibitors of bone resorption: inhibit osteoclasts activity and induce osteoclast apoptosis	70 mg/week (oral)	+	+	+	Oral bisphosphonates: low bioavailability due to low absorption in gastrointestinal tract (<1%) Long-lasting residual protection of bone Oesophageal irritation Flu-like symptoms after intravenous injection Osteonecrosis of the jaw in patients given high doses Atypical fractures of the femur with long-term use
	Risedronate		35 mg/week (oral)	+	+	+	
	Ibandronate		150 mg/month (oral) or 3 mg/3 months (IV)	+	Post hoc	–	
	Zoledronate		5 mg/year (IV)	+	+	+	
SERMs	Raloxifene	Inhibitors of bone resorption: non-steroidal agents that bind to the oestrogen receptor and act as oestrogen agonists on bone	60 mg/day (oral)	+	Post hoc	–	Decreased risk of invasive breast cancer due to oestrogen antagonist effects Increase in deep venous thromboembolism
	Bazedoxifene		20 mg/day (oral)	+	Post hoc	–	
Anti-RANKL monoclonal antibodies	Denosumab	Inhibitors of bone resorption: humanised monoclonal antibodies binding selectively and with high affinity to RANKL. Prevent the effect of RANKL on	60 mg/6 months (SC)	+	+	+	Possible adverse immune effects (dermatological side effects and skin infection) Hypocalcaemia Possibly associated with osteonecrosis of the jaw and atypical fractures of the femur Possible rebound of bone turnover and BMD loss after

		osteoclast differentiation, activation and survival					discontinuation
Parathyroid hormone	Teriparatide	Activators of bone formation: intermittent administration of PTH increases the number and activity of osteoblasts	20 µg/day (SC)	+	+	–	Contraindicated in conditions with abnormally increased bone turnover (pre-existing hypercalcaemia, primary hyperparathyroidism, Paget's disease of the bone, unexplained elevation of alkaline phosphatase) in patients with prior radiation therapy to the skeleton, skeletal malignancies or bone metastases Duration of treatment limited to 24 months (=duration of trial)
	PTH 1-84		100 µg/day (SC)	+	–	–	

The main mechanisms of action together with the clinical evidence of efficacy are reported.

IV, intravenous; RANKL, receptor activator of nuclear factor kappa B ligand; SC, subcutaneous; SERMS, selective oestrogen-receptor modulators; +, effect on fracture demonstrated; –, effect on fracture not demonstrated.

Most of these drugs decrease osteoclastic activity (bisphosphonates, denosumab, selective oestrogen-receptor modulators). The only bone anabolic agent registered for the treatment of osteoporosis is PTH, either the first 34 amino acids or the full molecule. The fundamental differences between these two classes of agents are illustrated in figures 2–4.

Figure 2 Components of spine bone mineral density (BMD) changes during therapy with antiresorptive drugs. The initial rapid increase in BMD is explained by the rapid reduction in the number of bone metabolic units (BMU). The decreased bone turnover associated with inhibitors of bone resorption permits a higher degree of secondary mineralisation (continuous process of mineralisation of mature bone tissue).

Figure 3 Changes in bone turnover markers during therapy with antiresorbers. The antiresorbers, such as bisphosphonates, rapidly decrease osteoclastic activity and bone resorption. This is associated with a later decrease in osteoblastic activity and bone formation. The lag time to new coupling between bone resorption and formation represents the therapeutic window, during which bone tissue is growing.

Figure 4 Changes in bone turnover markers during therapy with parathyroid hormone (PTH). PTH is the only bone anabolic agent so far available. It rapidly increases osteoblastic activity and bone formation. This is associated with a later increase also of osteoclastic activity and bone resorption. The lag time to new coupling between bone resorption and formation represents the therapeutic window, during which bone tissue is growing.

4.2.1 Bisphosphonates

Bisphosphonates (alendronate, risedronate, ibandronate and zoledronic acid; see table 6) are the accepted first-line therapy for most patients with postmenopausal osteoporosis. Drugs in this class increase bone strength and reduce fracture risk by inhibiting osteoclast activity and inducing osteoclast apoptosis, thereby reducing bone resorption and increasing BMD (Rodan and Reszka, 2002). Oral formulations are available for administration daily (alendronate, risedronate), weekly (alendronate, risedronate) and monthly (ibandronate, risedronate). Oral bisphosphonates are poorly absorbed (<1%) and might be associated with oesophageal irritation/gastrointestinal symptoms when used in clinical practice. They must be taken with plain water on an empty stomach after an overnight fast, with a post-dose fast and upright position for 30 min (alendronate, risedronate) or 60 min (ibandronate). Two intravenous bisphosphonates are approved by the European Medicines Agency (EMA) for the treatment of postmenopausal osteoporosis: ibandronate and zoledronic acid. The major side effect of these formulations is the occurrence 24–36 h after the first infusion, in a large proportion of patients, of flu-like symptoms or acute phase reaction (Rizzoli *et al*, 2011). The symptoms are almost invariably self-limiting, can be easily controlled with simple analgesics, and tend not to occur with subsequent infusions. In a few cases the symptoms might be long lasting and rather severe. This condition can be easily resolved with administration of paracetamol for 1–3 days.

A clinical entity termed osteonecrosis of the jaw (ONJ) has been described mostly in patients with malignancy given high intravenous doses of bisphosphonates (Cartsos *et al*, 2008). It is defined as necrotic bone exposed in the maxillofacial region lasting for more than 8 weeks in patients treated with bisphosphonate or

denosumab who have not undergone head and neck radiation therapy. The syndrome is characterised by difficulty in eating and speaking, oral pain, infection and bone necrosis. The condition commonly manifests as a painful exposed non-healing bone and is a challenging clinical and surgical management problem. Risk factors for the development of ONJ are: cancer and anticancer therapy, dental extraction, oral bone manipulating surgery, poorly fitting dental appliances, intra-oral trauma, duration of exposure to bisphosphonate treatment, glucocorticoids, alcohol and/or tobacco abuse, and pre-existing dental or periodontal disease (Khosla *et al*, 2007). ONJ can also occur, extremely rarely, in patients receiving oral bisphosphonates for osteoporosis treatment, but its incidence even in high-risk patients (see above) is not known. Since ONJ is likely to be associated with actinomyces infection, the empiric recommendation is to perform intensive antiseptic (both local and systemic) treatment whenever a patient who has been on treatment for a long time with bisphosphonates has to undergo an invasive mouth intervention.

The long-term use of bisphosphonates has also been associated with atypical fractures of the subtrochanteric region and diaphysis of the femur. These fractures are considered as stress or insufficiency fractures, which do not normally heal. Suppression by antiresorptive therapy of intracortical remodelling at the site of the stress fracture impairs the processes by which stress fractures normally heal, and lead to progress to full fracture. The absolute risk of these fractures in patients on bisphosphonates is low, ranging from 3.2 to 50 cases per 100 000 person-years, but long-term use may be associated with higher risk (100 per 100 000 person years) (Shane *et al*, 2014*). When an atypical subtrochanteric fracture is found, it is recommended to image the contralateral side at the same time.

The efficacy of the different bisphosphonates is globally comparable, regardless of their mode of administration, bearing in mind that:

- ibandronate has demonstrated its ability to reduce the risk of non-vertebral fractures only in a subgroup of patients with higher risk, but has shown no significant effect on the risk for hip fracture alone
- zoledronate has shown a reduced risk of clinical vertebral fractures, non-vertebral fractures and hip fractures. It has also demonstrated its efficacy for preventing clinical fractures after a first hip fracture, and showed that this reduction was associated with reduced all-cause mortality (Eriksen *et al*, 2009).

These two points are summarised in table 6. Different intermittent dosing, mode (oral or intravenous) and frequency of administration (mainly weekly or yearly), provide several options for bisphosphonate treatment and more patient and physician choice. This issue is important to limit poor adherence to treatment.

4.2.2 Selective oestrogen-receptor modulators

Selective oestrogen-receptor modulators (SERMs) are non-steroidal agents that bind to the oestrogen receptor and act as oestrogen agonists or antagonists, depending on the target tissue. Raloxifene (60 mg/day) was the first SERM available for the prevention and treatment of postmenopausal osteoporosis. It demonstrated effects on fracture prevention that are restricted to vertebral fractures (table 7). It should therefore probably not be considered as first-line therapy in women at high risk of non-vertebral fracture (particularly hip fracture). Other third generation SERMs have been developed, and bazedoxifene and lasofoxifene are now approved for the treatment of postmenopausal women in the EU (Silverman *et al*, 2008; Cummings *et al*, 2010). They decrease the incidence of vertebral fractures; a decrease of non-vertebral fractures was also demonstrated with lasofoxifene (at a dose of 0.5 mg/day), and in a subgroup of women at high risk of fractures (T score below -3 and/or one or more moderate or severe vertebral fractures) with bazedoxifene 20 mg/day (but not 40 mg/day).

Table 7 Raloxifene risk-benefit

Raloxifene benefit	Raloxifene risk
<ul style="list-style-type: none"> • Vertebral antifracture efficacy • Marked reduction in the risk of breast cancer • Cost-effectiveness profile 	<ul style="list-style-type: none"> • Lack of effect on non-vertebral fractures • Increased incidence of hot flashes • Risk of venous thromboembolism

The main adverse event of SERMs is an increase in deep venous thromboembolism. Particularly in early post menopause, climacteric symptoms may worsen. This is balanced by a decreased risk of invasive breast cancer (Barrett-Connor *et al*, 2006). Raloxifene does not significantly affect the risk of coronary heart disease and more generally of cardiovascular diseases. According to these data, raloxifene is considered to have a favourable risk:benefit ratio in the treatment of osteoporosis in early postmenopausal osteoporotic women at risk of vertebral fractures.

4.2.3 Denosumab

Denosumab is the latest antiresorptive agent approved for osteoporosis treatment in the EU. Denosumab is a humanised monoclonal antibody that binds selectively and with high affinity to the receptor activator of nuclear factor κ B ligand (RANKL, a member of the tumour necrosis factor (TNF) family). This is a major cytokine involved in osteoclast activation and bone remodelling expressed by osteoblasts, synovial fibroblasts and activated T cells. RANKL binds to RANK, a receptor on osteoclast membranes, and induces differentiation, activation and survival of osteoclasts. A regulator of the RANK–RANKL interaction is the soluble cytokine osteoprotegerin (OPG), which functions as a decoy receptor by competing for binding to RANK. Denosumab mimics the effect of OPG on RANKL (Kearns *et al*, 2008).

The optimal dose of denosumab, one subcutaneous injection of 60 mg every 6 months, is associated with a continuous increase of BMD over the years, with some disparities versus bisphosphonate effects (Lewiecki et al, 2007; Miller et al, 2008; Brown et al, 2009):

- A decrease in serum CTX (C-telopeptide of type 1 collagen) levels, a bone resorption marker, occurs rapidly, as early as 3 days after the injection. After treatment discontinuation, bone turnover transiently rebounds above baseline values and most of the BMD gains are lost after 12 months.
- Denosumab demonstrated significantly greater gains in BMD (3.5% vs 2.6% at total hip at 12 months), and greater reduction in bone turnover markers compared with alendronate. In the denosumab extension study (up to 10 years of treatment with denosumab), BMD continuously increase.
- In contrast to bisphosphonates, denosumab has no residual effect.

The results of a phase III fracture trial using a dose of 60 mg subcutaneously every 6 months was published in 2009. In 7808 women with osteoporosis followed for 3 years, denosumab reduced the risk of new vertebral fractures by 68% (2.3% denosumab vs 7.2% placebo; $p < 0.001$), the risk of hip fractures by 40% (0.7% denosumab vs 1.2% placebo; $p = 0.036$), and the risk of non-vertebral fractures by 20% (6.5% denosumab vs 8% placebo; $p = 0.011$) (Cummings et al, 2009).

Regarding potential adverse events, concerns about possible adverse immune effects of denosumab are still debated. This is biologically plausible since RANKL is expressed on activated T and B lymphocytes, which, in the lymph nodes, are responsible for recognition of foreign antigens. Nevertheless, there is no evidence of impaired immunity in humans treated with denosumab. Skin infections (cellulitis erysipelas) and other skin-related conditions (eczema) were reported in denosumab-treated patients. Clinicians should provide adequate calcium and vitamin D supplementation to limit the risk of hypocalcaemia following denosumab administration, which appears to be higher than with bisphosphonates. ONJ and atypical fractures of the femur have also been described with denosumab, associated with its effects on bone resorption. The efficacy and safety of association of biological agents targeting cytokines such as TNF or interleukin 6 (IL-6), and denosumab, will need to be specifically investigated in the treatment of rheumatoid arthritis and other inflammatory diseases. Reassuring data have been recently published showing that the rate of hospitalized infections among patients with rheumatoid arthritis receiving denosumab concurrently with biologic agents was not increased compared to those receiving zoledronate (Curtis et al, 2015).

Discontinuation of denosumab is associated with a transient increase in bone resorption and decline in BMD, to check. Some cases of multiple vertebral fractures have been reported in this context (Lamy et al, 2016), although it remains unclear whether these fractures are related to the rebound of bone turnover or to the fact that the patients in which they occur are at particularly high risk of fracture (Brown et al, 2013). Thus, CTX levels should be regularly monitored after denosumab discontinuation. Recent data indicate that prior

exposure to bisphosphonates may prevent the rebound of bone turnover markers after denosumab discontinuation (Uebelhart et al, 2016). In case of bone resorption rebound, oral bisphosphonates for a few months or one zoledronic acid injection should be added. This attitude is indirectly supported by the data of the DAPS (Denosumab Adherence Preference Satisfaction) study, in which no BMD loss was observed after denosumab discontinuation in the group of postmenopausal women, with no prior bisphosphonate use, who received denosumab then alendronate over successive 12-month periods (Freemantle et al, 2012).

4.2.4 PTH family

The continuous endogenous production of PTH, as seen in primary or secondary hyperparathyroidism, can lead to harmful consequences for the skeleton, particularly on cortical bone. However, intermittent administration of PTH (eg, with daily subcutaneous injections) results in an increase in the number and activity of osteoblasts, leading to an increase in bone mass and an improvement in skeletal architecture at both cancellous and cortical skeletal sites (Black et al, 2003; Hodsman et al, 2005). At present, PTH is the only available anabolic agent, with two available peptides: teriparatide or recombinant PTH 1-34, and the intact recombinant hormone PTH 1-84.

The most common reported adverse events in patients treated with PTH or teriparatide are nausea, pain in the limbs, headache and dizziness. In normo-calcaemic patients, slight and transient elevations of serum calcium concentrations have been observed following the injection of PTH or teriparatide, which are usually dealt with by discontinuation of calcium supplements.

The use of peptides of the PTH family is contraindicated in conditions characterised by abnormally increased bone turnover (eg, pre-existing hypercalcaemia, metabolic bone diseases other than primary osteoporosis, including primary hyperparathyroidism and Paget's disease of the bone, unexplained elevation of alkaline phosphatase, prior external beam or implant radiation therapy to the skeleton, or in patients with skeletal malignancies or bone metastases).

The duration of treatment is limited in Europe to no more than 24 months (the median duration of the pivotal trials was 19 months). The safety data indicate that the expected incidence in the exposed population adjusted for age is identical to that of the general population. Teriparatide has demonstrated its efficacy for preventing both vertebral and non-vertebral fracture, whereas PTH 1-84 has demonstrated its efficacy for preventing vertebral fractures only. There is an initial brisk increase in markers of bone formation (P1NP) within days or weeks of initiating teriparatide. Bone formation marker levels usually peak within 1 year (varying for the specific marker measured) and begin to decline thereafter towards baseline, despite continued treatment. Increases in markers of bone resorption are delayed until after 1 month, but also peak and decline towards baseline during the second year of teriparatide. The increase in spine BMD after teriparatide is also most rapid within the first 6 months, consistent with the biochemistry (Cosman et al 2015).

Due to their elevated cost, teriparatide and PTH 1-84 are used in most countries only in patients with severe osteoporosis.

4.2.5 Hormone replacement therapy

For several decades, hormone replacement therapy (HRT) was widely used for the treatment or prevention of osteoporosis on the basis of surrogate endpoints. The Women's Health Initiative study provided the first solid evidence of its efficacy to reduce the risk of both clinical vertebral fracture and non-vertebral fracture (including hip). However, the results of the same study also indicated that HRT is associated with an increased risk of breast cancer, cardiovascular diseases and stroke. It appeared that the long-term risks of HRT outweigh the benefits and for this reason the indication for HRT for osteoporosis treatment was cancelled by the EMA (Rossouw et al, 2002).

4.3 Combination and sequential treatments

The combination of two antiresorbers (eg, HRT with a bisphosphonate) is associated with greater decreases in bone resorption and greater increases in BMD than either agent alone. These combinations might be used in limited cases—for example, in women with low oestrogen doses with persistent high turnover.

Patients pre-treated with inhibitors of bone resorption, who have not achieved a full therapeutic response, are good candidates for treatment with anabolic agents. However, the combination of an antiresorptive agent and either PTH or teriparatide is associated with bone mass changes generally lower than those obtained with PTH alone. There are data suggesting that the administration of an inhibitor of resorption (bisphosphonate or SERM) after treatment with PTH prevents the rapid bone loss observed after treatment discontinuation (Black et al, 2005). Therefore, the administration of inhibitors of bone resorption is strongly recommended after a treatment course with PTH or teriparatide. More recently, it has been shown that combination of teriparatide and denosumab was associated with higher BMD gain than each one of these treatment alone, suggesting that this combination may be of potential interest in postmenopausal women with a very high risk of both vertebral and non-vertebral fractures.

4.4 First choice treatment

In the absence of head-to-head studies that directly compare the drugs for antifracture efficacy, there is no evidence to allow conclusions on differences among drugs. Surrogate markers (i.e., effects on BMD or biochemical markers) cannot help in this matter in clinical practice.

Anti-osteoporotic agents include drugs that can increase bone formation (such as teriparatide and PTH) or decrease bone resorption (such as bisphosphonates, raloxifene and denosumab). One could expect that the choice between these agents may be driven by bone remodelling (i.e., a bone-forming agent in the case of low

turnover and an antiresorptive drug in the case of high turnover). However, current data do not support this concept. There are no convincing data to suggest that serum CTX or PINP (procollagen type I N propeptide), currently the most relevant markers of bone resorption and formation, respectively, may help in choosing the first anti-osteoporotic drug.

In early postmenopausal subjects, considering that the risk of vertebral fractures is higher than the risk of hip fractures, and that sequential therapies will probably be necessary, drugs with demonstrated effectiveness at all sites should not necessarily be preferred to one without demonstration at the hip, for example. It has to be kept in mind that demonstration of a fracture risk reduction at a specific site (i.e., vertebral versus non-vertebral fractures) can be achieved statistically in populations with high risk of fractures at this site in particular. Studies evaluating as the primary outcome the effect of drugs on vertebral fracture risk were not necessarily designed to demonstrate a decrease in non-vertebral fracture risk in the same population during the same length of follow-up.

Thus, the decision is based on (table 8) (Geusens et al, 2008*; Rizzoli et al, 2011):

- the characteristics of patients (age, climacteric symptoms, gastrointestinal intolerance)
- the characteristics of the disease (main risk at the spine, the hip or both)
- the characteristics of the drug (similarity between the real-life patients and the patients enrolled in the pivotal studies of the drug)
- the patient preference that influences long-term patient adherence to treatment. The prescribers must be aware that one determinant of effectiveness is adherence to treatment, so the information given to the patient must be optimal, and low persistence and compliance must be anticipated. The cost of the drug is also an important determinant of treatment adherence in some countries.

Table 8 Main factors influencing treatment choice in addition to evidence of efficacy (see table 6)

Most relevant individual concern	Drug of first choice
Gastrointestinal intolerance	Intravenous ibandronate or zoledronate, raloxifene, denosumab
Convenience	Monthly ibandronate, intravenous zoledronate, denosumab
Cost of treatment	Generic alendronate, generic risendronate, generic zoledronate
High risk of breast cancer	Raloxifene
Postmenopausal symptoms in patients <60 years old	Hormone replacement
Severe osteoporosis	Teriparatide, PTH 1-84

4.5 Duration of treatment and drug holidays

Osteoporosis requires long-term treatment to prevent fracture and its damaging consequences in the elderly, but efficacy against fracture should be balanced against the risk of adverse events. The drug and duration of treatment will depend on individual patient characteristics and the severity of osteoporosis (new incident fracture, levels of BMD) (Cooper *et al*, 2012). Data are available from study extensions over periods of 10 years for alendronate and denosumab, 7 years for risedronate, 8 years for raloxifene, and 6 years for zoledronic acid. It appears appropriate to evaluate treatment (clinical risk factors, BMD variation, incident fractures, including vertebral fractures assessed by back pain and/or height loss of 2 cm or more during follow-up, radiographs of the spine or vertebral fracture assessment) after 5 years of treatment, and after 3 years for zoledronic acid (Adler *et al*, 2016). Long-term treatment often consists of the sequential use of several osteoporosis drugs. There is no scientific evidence supporting a specific treatment sequence, the only exception being teriparatide followed by a bone resorption inhibitor. Several factors guide the clinician in selecting drugs in an individual patient (health insurance reimbursement restrictions, severity of the osteoporosis, predominant risk of peripheral fractures, comorbidities, contra-indications to specific drugs, and patient adherence to prescriptions).

With regards specifically to long-term bisphosphonate use, questions are often raised about optimal duration of therapy. As alluded to above, there is no evidence base beyond 10 years to guide treatment. Pivotal clinical trials have mainly been limited to duration of 3 years with recommendations for drug holidays and longer term treatment based on limited evidence from extension studies in post-menopausal women. Withdrawal of treatment is associated with decreases in BMD and increased bone turnover after 2–3 years for alendronate and 1–2 years for ibandronate and risedronate (Compston *et al*, 2017). In the Health Outcomes and Reduced Incidence with Zoledronic acid Once Yearly (HORIZON) study extension, withdrawal of zoledronic acid after 3 years' treatment was associated with only a very small decrease in BMD and bone markers after a further 3 years without treatment. Moreover, a post hoc analysis of subgroups of subjects from the HORIZON-PFT and HORIZON-RFT studies who received only one infusion of zoledronic acid, assessed fracture incidence in these patients. There was a 32% reduction in clinical fracture with zoledronic acid given once versus placebo over 3 years of follow-up, which is comparable with the fracture reduction seen in those who had three or more annual infusions (Reid *et al*, 2013). These data indicate that the effects of a single dose of zoledronic acid on BMD and bone turnover last for much more than 1 year. Drug holidays have therefore been defined as being between 1-3 years, varying by drug, on the above basis.

Nevertheless, it was also seen that the risk of morphometric vertebral fractures was significantly lower in women continuing on zoledronic acid for 3 years after 3 years therapy when compared with those switched to placebo, but the risk of non-vertebral fractures was similar in the treatment and placebo groups. (Black *et al*, 2012). In the Fracture Intervention Trial Long-term Extension study of alendronate (FLEX), there were

significantly fewer clinical vertebral fractures in women previously treated with alendronate for 5 years who continued with alendronate for five more years than in those assigned to placebo after 5 years of alendronate (Black et al, 2006). Post hoc analyses from the alendronate and zoledronic acid extension studies suggest that women most likely to benefit from long-term bisphosphonate therapy are those with low hip BMD (T-score < -2.0 in FLEX and \leq -2.5 in HORIZON), those with a prevalent vertebral fracture and those who sustained one or more incident fractures during the initial 3 or 5 years of treatment. Older age was also associated with increased fracture risk after discontinuation of alendronate therapy (Compston et al, 2017).

The UK National Osteoporosis Guideline Group (NOGG) has generally advised continuation of bisphosphonate treatment beyond 3–5 years (3 years for zoledronic acid and 5 years for alendronate, ibandronate and risedronate) for the following situations:

- Age 75 years or more
- Previous history of a hip or vertebral fracture
- Occurrence of one or more low trauma fractures during treatment, after exclusion of poor adherence to treatment (for example less than 80% of treatment has been taken) and after causes of secondary osteoporosis have been excluded
- Current treatment with oral glucocorticoids \geq 7.5 mg prednisolone/day or equivalent

If treatment is discontinued after a course of treatment on the basis of FRAX below intervention threshold and hip BMD T-Score > -2.5, fracture risk should be reassessed:

- After a new fracture regardless of when this occurs
- If no new fracture occurs, after 18 months to 3 years

Although not in widespread clinical use, the residual effect of bisphosphonates in bone can be monitored using beta-crosslaps levels (CTX), a bone resorption marker, to guide treatment efficacy or retreatment, the objective being to maintain CTX levels in the lower limit of the normal premenopausal range.

We make a note here that strontium ranelate will no longer be manufactured in Europe beyond August 2017 and has not previously been approved for use in the USA by the FDA. The manufacturer chose to do this because use was declining with the restrictions in place limiting its use to patients unable to take other medications for osteoporosis and who did not have a history of heart disease or a history or high risk of venous thromboembolism (Reginster et al, 2015) due to increases in cardiovascular risk and venous thromboembolism with the drug. Patients currently on strontium will need their treatment regimen reviewed.

4.6 Treatment efficacy and failure

Failure of treatment can be inferred when:

- two or more incident fractures have occurred during treatment
- serial measurements of bone remodelling markers are not suppressed by antiresorptive therapy
- BMD continues to decrease.

It has to be noted that treatment failure can be considered only after checking for adequate calcium and vitamin D intakes, and greater than 80% treatment adherence (Diez-Perez *et al*, 2012).

5 Glucocorticoid-induced osteoporosis

5.1 General management

Osteoporosis is the most debilitating complication of glucocorticoid therapy. Thus, glucocorticoids should be prescribed at the lowest possible dose and for the shortest possible duration, as the fracture risk increases with increasing daily dose, cumulative doses, and treatment duration.

The non-pharmacological measures to prevent fractures for glucocorticoid-induced osteoporosis (GIOP) are similar to those recommended for other causes of osteoporosis.

As intestinal calcium absorption is impaired by glucocorticoid therapy, a diet rich in calcium or calcium supplements is recommended, even though evidence of efficacy is lacking and calcium alone is definitely not sufficient to prevent rapid bone loss in patients starting high-dose glucocorticoids.

Cholecalciferol plus calcium or vitamin D metabolites are somewhat more efficacious in preserving BMD than no therapy, but the overall effect is modest. Nowadays, it is highly recommended that all patients on chronic glucocorticoid treatment have an adequate calcium intake (eg, >1000 mg/day) and 25(OH) vitamin D levels well within the normal range (eg, >30 ng/mL or 75 nmol/L). Weight-bearing exercise is recommended if the underlying condition allows this in order to maintain muscle mass, which could be potentially endangered by glucocorticoid therapy.

5.2 Threshold for a pharmacological intervention

The risk of fracture in patients taking pharmacological doses of glucocorticoid is related to daily dose and only in part to cumulative dose, and it is mostly independent of BMD. An analysis of the placebo groups of randomised clinical trials found that glucocorticoid users had considerably higher risks of vertebral fracture at the same levels of BMD than controls.

Thus, glucocorticoid therapy influences fracture risk by a mechanism independent of BMD, which amplifies the risk of fracture associated with low BMD and other typical risk factors for osteoporotic fractures (Rizzoli *et al*, 2012b).

Treatment thresholds for pharmacological interventions are nowadays set in terms of fracture risk over a limited lag time, assessed by FRAX. Specific considerations regarding fracture risk assessment in patients taking glucocorticoids are as follows:

- There is a dose relationship between glucocorticoid use for more than 3 months and fracture risk. The average dose exposure captured within FRAX is likely to be a prednisone dose of 2.5–7.5 mg/day or its equivalent. Fracture probability is under-estimated when prednisone dose is greater than 7.5 mg/day and is over-estimated when the prednisone dose is less than 2.5 mg/day. The proposed adjustments are: ($\times 0.8$) if glucocorticoids ≤ 2.5 mg/day, and ($\times 1.15$) if glucocorticoids ≥ 7.5 mg/day for major fracture probability; and ($\times 0.65$) if glucocorticoids ≤ 2.5 mg/day, and ($\times 1.20$) if glucocorticoids ≥ 7.5 mg/day for hip fracture probability (Kanis *et al*, 2011).
- Frequent intermittent use of higher doses of glucocorticoids increases fracture risk. Because of the variability in dose and dosing schedule, quantification of this risk is not possible.
- High-dose inhaled glucocorticoids may be a risk factor for fracture. FRAX may underestimate fracture probability in users of high-dose inhaled glucocorticoids.
- Appropriate glucocorticoid replacement in individuals with adrenal insufficiency has not been found to increase fracture risk. In such patients, use of glucocorticoids should not be included in FRAX calculations.

As the incidence of fracture increases rapidly after the initiation of glucocorticoid therapy, a therapeutic intervention is generally strongly recommended as soon as glucocorticoids are started (particularly for postmenopausal women), thus making the distinction between primary prevention (initiation of bone protective therapy at the time glucocorticoids are initiated) and secondary prevention (that bone protection is started later in the course of glucocorticoid therapy) not really relevant.

The most recent recommendations are reported in table 8. IOF-ECTS GIOP guidelines recommend a pharmacological intervention in men and women over the age of 50 years committed or exposed to ≥ 3 months of oral glucocorticoids, in individuals with a history of previous fractures, or older than 70 or receiving prednisolone ≥ 7.5 mg/day. In other situations, fracture risk assessment using FRAX with or without BMD should help to determine if the patient's risk has reached the intervention threshold adapted to the particular country. In younger people, the evidence base is limited: a previous fracture should be considered, but otherwise, treatment decisions are based on clinical judgment (Lekamwasam *et al*, 2012).

Country-specific restrictions for drug reimbursements often include a minimum daily dose and treatment duration for glucocorticoid.

Table 8 Intervention threshold for glucocorticoid-induced osteoporosis in postmenopausal women and men >50 yrs in recent recommendations

	ACR 2010	IOF/ECTS 2012	SFR 2014	NOF 2014
Glucocorticoids	≥ 7.5 mg/day ≥ 3 months if low risk; any dose ≥ 3 months if medium risk; no dose threshold if high risk	≥ 7.5 mg/d ≥ 3 months	≥ 7.5 mg/d ≥ 3 months	
Age		OR ≥ 70 yrs	OR ≥ 70 yrs	
Prior fracture		OR Fragility fracture	OR Fragility fracture	Fragility fracture
DXA T-score			OR T-score ≤ -2.5	OR T-score ≤ -2.5
FRAX	AND FRAX MOF: ≤ 10 % : low risk 10-20 % : medium risk >20 % : high risk	OR FRAX* > intervention threshold of general population	OR FRAX* > intervention threshold of general population	AND FRAX >20% MOF or >3% hip fracture

5.3 Pharmacological intervention

Fracture reduction has not been a primary endpoint in any of the intervention studies in GIOP. Thus, evidence for antifracture efficacy has to be derived from post hoc analyses, meta-analyses or safety data, invariably limited to vertebral fractures (Rizzoli and Biver, 2014).

Vitamin D metabolites, calcitonin, etidronate, pamidronate and clodronate have been tested in the past for the treatment of GIOP, but the trials never provided sufficiently robust results.

The bisphosphonates alendronate, risedronate and zoledronic acid are licensed in both Europe and North America for GIOP therapy. A Cochrane Review of the effects of bisphosphonates in the prevention and treatment of GIOP concluded that there were significant treatment benefits for lumbar spine and proximal femur BMD, which were generally somewhat lower than those observed in postmenopausal women. However, the 24% reduction in the odds of spinal fractures did not reach statistical significance.

A randomised clinical trial compared the effect on BMD (primary endpoint) and fracture risk (secondary endpoint) of subcutaneous teriparatide (20 µg/day) and oral alendronate (10 mg/day) therapy for 36 months in patients with GIOP. Teriparatide resulted in significantly greater increases in lumbar spine and hip BMD compared with alendronate, and was associated with significantly fewer patients with new vertebral fractures in the teriparatide group (Saag *et al*, 2009).

The results of this study are not surprising. GIOP is primarily a disorder characterised by reduced bone formation, which is expected to benefit from an anabolic approach rather than antiresorbers. Based on these data and its high cost, teriparatide treatment may be considered a therapeutic strategy for GIOP patients at high fracture risk.

6 Osteoporosis in men

6.1 General management

Male osteoporosis remains under-diagnosed, probably because of the common perception that osteoporosis is a disease of women, and the existence of an underlying cause in 50% of men with osteoporosis. Male osteoporosis is also clearly undertreated, since 15% of men older than 50 years will experience at least one osteoporotic fracture at some point, an event associated with higher morbidity and mortality rates than in women (Liu *et al*, 2008). Ensuring adequate calcium and vitamin D intake, and appropriate physical activity, is essential. Lifestyle factors known to be associated with bone loss should be avoided (eg, alcohol, tobacco).

6.2 Pharmacological intervention

Several drug classes are now available for treating male osteoporosis. For drugs allowed for the treatment of postmenopausal osteoporosis in women at high risk of fracture, bridging studies using the same formulation, dose and route of administration in male osteoporotic patients were considered as sufficient by the EMA for granting these drugs a marketing authorisation with the indication 'treatment of osteoporosis in men at increased risk of fracture', provided that:

- the duration of the study is at least 1 year
- the dosage is justified
- the applicant justifies that the cut-off of BMD, age and any other risk factor chosen for the inclusion of men in the pivotal study will generate a fracture risk of a similar magnitude compared with postmenopausal women who were recruited in the studies used to obtain the indication 'treatment of postmenopausal osteoporosis in women at increased risk of fracture'

- the magnitude of the changes in BMD versus placebo is similar to that observed in postmenopausal osteoporotic women treated with the same compound and is proportional to the decreased incidence of fractures in treated women.

Compared to studies in postmenopausal osteoporotic women, studies evaluating these drugs in male osteoporosis are characterised by considerably lower sample sizes (about 100 versus 1000 patients per group), shorter follow-up durations (2 years at most), and very few data on the occurrence of fractures. A recent report with new morphometric vertebral fractures as the primary endpoint indicates an antifracture efficacy of intravenous zoledronic acid in osteoporotic men, with the same trend as observed in women (Boonen *et al*, 2012).

Thus, alendronate, risedronate, zoledronic acid, and teriparatide are effective in male osteoporosis and have been validated in this indication by the EMA (Orwoll *et al*, 2000; Orwoll *et al*, 2003; Finkelstein *et al*, 2003; Boonen *et al*, 2009; Orwoll *et al*, 2010). They improve BMD in men, regardless of age and gonadal function. Indications for using these drugs should be based on absolute fracture risk.

6.3 Secondary osteoporosis in men

Secondary causes of osteoporosis should be identified and treated.

Data on the effect and safety of testosterone replacement therapy on bone density and fracture risk in men are lacking. Testosterone replacement therapy is appropriate for the management of hypogonadal syndrome, but the treatment of osteoporosis in a man with low testosterone levels is most likely undertaken with a bisphosphonate or PTH (Martin, 2011).

Androgen-deprivation therapy (ADT) for the treatment of prostate cancer is now a major secondary cause of osteoporosis. Bisphosphonate therapy prevents the bone loss associated with such therapy. Denosumab significantly reduces vertebral fracture risk in men on ADT (Smith *et al*, 2009).

GIOP is also a frequent cause of male osteoporosis.

7 Potential new drugs for osteoporosis

7.1 Novel antiresorptive agents

The development of odanacatib, a cathepsin K inhibitor, has recently been stopped because of a higher incidence of stroke in the treatment arm of the studies testing the effect of odanacatib in postmenopausal osteoporosis. Cathepsin K is a cysteine protease enzyme selectively expressed by osteoclasts, which is required to resorb bone matrix proteins including collagen.

7.2 Novel anabolic agents

Romosozumab, a monoclonal anti-sclerostin antibody, targets Wnt signalling, a pathway that regulates gene transcription of proteins important for osteoblast function such as β -catenin (Baron and Kneissel, 2013). Inhibitors of Wnt signalling, such as sclerostin or DKK1, decrease bone formation, while deficiencies in the inhibitors or antibodies to them result in increased Wnt signalling and bone formation. Sclerostin is an osteocyte-derived inhibitor of osteoblast activity. Romosozumab binds to sclerostin and increases bone formation. In a phase II trial in postmenopausal women, romosozumab (210 mg subcutaneous monthly) increases BMD at the lumbar spine more than placebo, alendronate or teriparatide. This positive effect on BMD was associated with a transitory increase (greatest at 1 month) in P1NP, a bone-formation marker, and a sustained decrease in CTX, a bone-resorption marker (McClung et al, 2014). The phase 3 Fracture Study in Postmenopausal Women with Osteoporosis (FRAME) (n=7180) has been reported in 2016, showing that romosozumab lowers the risk of vertebral fractures compared to placebo at 12 months, then from months 12-24 both groups received 6 monthly 60mg S/C denosumab and the romosozumab group continued to have a lower risk of vertebral fracture 0.6% vs 2.5% (Cosman et al, 2016). Perhaps surprisingly, one atypical femoral fracture and two cases of osteonecrosis of the jaw were observed in the romosozumab group.

A press release from the manufacturer in May 2017 from a different phase 3 study has indicated in a primary analysis that treatment with romosozumab for 12 months followed by alendronate significantly reduced the incidence of new vertebral fractures through 24 months, clinical fractures (primary endpoints) and non-vertebral fractures (key secondary endpoint) in postmenopausal women with osteoporosis at high risk for fracture, compared to alendronate alone. However, an imbalance in positively adjudicated cardiovascular serious adverse events was observed as a new safety signal (2.5 percent romosozumab versus 1.9 percent alendronate at 12 months).

Abaloparatide, a selective activator of the parathyroid hormone type 1 receptor, is another bone anabolic agent which reduces the incidence of new vertebral fractures and nonvertebral fractures compared with placebo when studied over 18 months. Hypercalcemia may be less frequent with abaloparatide than with teriparatide (Miller, 2016). This study was extended to then offer both groups alendronate straight after the 18 months and a published interim analysis at a further 6 months shows a relative risk reduction of new morphometric vertebral fractures by 87% and lower estimated rates of non-vertebral fractures (risk reduction 52%) in the abaloparatide/alendronate group versus placebo/alendronate group (Cosman et al, 2017). In April 2017, subcutaneous abaloparatide received its first global approval, in the USA, for the treatment of postmenopausal women with osteoporosis at high risk for fracture (defined as a history of osteoporotic fracture, multiple risk factors for fracture, or patients who have failed or are intolerant to other available osteoporosis therapy).

The calcium sensing receptor (CaSR) is a G protein-coupled, seven-pass transmembrane molecule present in the parathyroid gland and kidney which monitors and controls calcium homeostasis by releasing PTH (Brown, 2007). Manipulation of the receptor by small molecule allosteric modulators can either decrease or increase PTH secretion (calcilytic agents). One of these agents (ronacaleret) has shown a robust PTH response associated with increases in both cortical and trabecular bone formation, but its development has been terminated because of insufficient efficacy in clinical trials.

SUMMARY POINTS

- Any pharmacological intervention for postmenopausal osteoporosis and osteoporosis of the elderly should be preceded and accompanied by the elimination of risk factors: inadequate intake of calcium and vitamin D, smoking, low physical activity, excess alcohol intake.
- Among elderly people, vitamin D deficiency is extremely common and may severely jeopardise the outcomes from pharmacological interventions.
- Preventive measures should be recommended to all elderly subjects and in women after the menopause with risk factors.
- All pharmacological agents registered for the treatment of postmenopausal osteoporosis have evidence of efficacy on vertebral fracture risk. The same evidence for non-vertebral fracture is rather inconsistent.
- Antiresorbers (bisphosphonates, denosumab, raloxifene) are the most commonly used drugs for the treatment of osteoporosis. Most of the beneficial effects on bone mineral density (BMD) are achieved during the first year, provided that calcium and vitamin D deficiency is corrected.
- A pharmacological treatment is recommended when fracture risk is considered unacceptable, and this threshold may vary individually. Clinical risk factors and FRAX can help to assess fracture risk, although there is no universal threshold intervention associated with the FRAX tool.
- In patients with a history of major osteoporotic fracture, treatment should be recommended independently of the bone densitometry assessment.
- Chronic use of glucocorticoids is associated with a dramatic increase in fracture risk. The risk rises soon after treatment initiation and it is considerably higher than that expected from the actual value of BMD or its changes.
- Alendronate, risedronate and zoledronic acid have been the only agents registered for the treatment of glucocorticoid-induced osteoporosis until the registration for the same condition of teriparatide, which has shown superior antifracture efficacy over alendronate. Teriparatide is likely to become the treatment of choice for patients with severe glucocorticoid-induced osteoporosis.

IN-DEPTH DISCUSSION I

**Vitamin D deficiency and response to treatment in
postmenopausal osteoporosis**

The registration of all available drugs for osteoporosis was obtained from the results of large randomized clinical trials (RCTs) demonstrating their ability to reduce fracture risk (Sambrook et al, 2006). All these clinical trials were conducted for patients with baseline 25-hydroxy-vitamin D (25OHD) within the normal range (with or without previous vitamin D supplements) and vitamin D supplements were provided all throughout the clinical trials to both active and control group. This implies that the reported benefits in terms of both increases in bone mineral density (BMD) and mainly reduced fracture risk can be expected only in vitamin D and calcium replete individuals.

In routine clinical settings this is not consistently achieved particularly for patients who do not get a qualified medical follow-up. A number of reasons may explain this. Vitamin D deficiency is extremely common among the elderly affecting proportions ranging from 40 to 100% (Holick et al, 2007). It is quite likely that both the prevalence and the severity of vitamin D deficiency are considerably greater among people requiring an osteoporosis treatment. Severe osteoporosis is very common among the elderly living in nursing homes and these patients are at high risk of vitamin D deficiency. Both the risk of vitamin D deficiency and the risk of osteoporosis rise with aging and the level of 25OHD are related to bone mineral density, fracture incidence and frailty (Isaia et al, 2003). Thus, people requiring pharmacological treatment for osteoporosis are likely to be at the highest risk of vitamin D deficiency for their osteoporosis (Bischoff-Ferrari et al, 2008). The patients participating on clinical trials for osteoporosis are generally younger and less frail than people on treatment for osteoporosis in a routine setting. More than 50% of postmenopausal women taking medications for osteoporosis were found to have suboptimal levels of 25OHD (below 30 ng/ml or 75 nmol/l) in the USA (Holick et al, 2005). In Italy, 35 % of the patients on pharmacological treatment for severe osteoporosis and followed by qualified osteoporosis centres had vitamin D deficiency (Adami et al, 2009). These findings are somewhat surprising since all guidelines recommend that any pharmacological intervention should be associated with calcium and vitamin D supplements. However, the implementation of these guidelines is hampered by a number of factors.

The definition of vitamin D insufficiency and deficiency has been changed only recently (Rizzoli et al, 2013) (table 1). From a number of different studies, it appears that 25OHD > 75 nmol/l are required in order to consistently prevent secondary hyperparathyroidism (Thomas et al, 1998; Holick et al, 2005), to achieve the genetically determined optimal bone mass and to optimize muscle strength (Bischoff-Ferrari et al, 2010). Intestinal calcium absorption is also dependant of 25OHD levels (Heaney et al, 2003). Many laboratories still report as normal levels of 25OHD > 10 ng/ml (25nmol/l), which are now considered totally inadequate for bone health.

Meta-analyses of vitamin D supplementation have provided evidence that a dose of 800UI/day vitamin D is required to achieve the correct daily allowance of vitamin D (Bischoff-Ferrari et al, 2012). This approach may be inadequate if the patient is vitamin D deficient and therefore deprived of appropriate vitamin D reserves.

However, the use of high loading doses of vitamin D at the outset of repletion has been reconsidered by recent data indicating that women receiving once annual high dose of oral cholecalciferol (500,000 IU) experienced more falls and fractures than the placebo group (Sanders et al., 2010). The causes of these effects remain speculative and need further studies. Similar observations on falls were found with lower loading doses (60 000 IU of vitamin D per month) versus 24 000 IU vitamin D per month in community-dwelling men and women 70 years and older (Bischoff-Ferrari et al, 2016). The specific vitamin D dosing regimen to correct vitamin D deficiency or insufficiency should use more frequent but low dose regimens for which there is no evidence of adverse effects (for example if the patient is vitamin D deficient, 1500-2000 IU vitamin D per day for one to three months followed by 800 IU vitamin D per day).

The impact of vitamin D deficiency on the response to treatment in postmenopausal osteoporosis has been occasionally underestimated. For example, from a post-hoc analysis of the MORE trial, it was concluded that vitamin D insufficiency does not affect the BMD response to raloxifene (Antoniucci et al, 2005). Regarding patients treated with bisphosphonates, it has been shown that patients with a mean 25(OH)D ≥ 33 ng/ml (82nmol/l) have a substantially greater likelihood of maintaining bisphosphonate favourable response (no T-score < -3 that persists between DEXA scans, no decrease in BMD higher than 3%, and no incident fracture on bisphosphonate therapy) (Carmel et al., 2012). The BMD changes were analysed according to individual 25OHD levels as measured at the time of randomization and they were found somewhat greater among vitamin D insufficient patients. Patients with vitamin D insufficiency are expected to exhibit greater changes in BMD from the vitamin D supplementation provided during clinical trials than people with normal 25OHD levels.

An additional problem may come from the way the problem of calcium and vitamin D supplementation is discussed with the patient. Typically, most osteoporotic patients are advised to take pharmacological formulations combining calcium salts to vitamin D. The treatment adherence to these formulations is modest due to the poor tolerability of calcium salts (Rossini et al, 2006). The general attitude is the recommendation of taking as much as possible of the prescription but the consequence may be that many patients, for the intolerance of calcium, get neither calcium nor vitamin D.

Providing adequate calcium intake is a puzzling problem for the many patients who are intolerant to both dairy products and calcium supplements. Calcium intake and 25OHD levels are both important determinants of PTH secretion (Steingrimsdottir et al, 2005; Adami et al, 2008).

The consequences of vitamin D deficiency on the treatment outcome of pharmacological treatment of osteoporosis are poorly understood since ad hoc prospective studies are ethically unconceivable. The only information comes from case reports or retrospective studies.

A study looking at the prevalence of inadequate response to anti-resorptive agents (alendronate, risedronate and raloxifene) in patients with severe osteoporosis showed that the inadequate supplementation with calcium and vitamin D was associated with 98% higher occurrence of clinical fracture (Adami et al., 2006). In a study evaluating retrospectively the treatment outcomes of at least one year therapy with anti-resorptive agents (Adami et al, 2009), it was reported that one third of the patients were vitamin D deficient. In those patients, BMD slightly decreased during the one year of observation while it raised by 2% in women replete with vitamin D. It was also observed that the proportion of patients with incident clinical fracture was almost double in vitamin D deficient as compared to vitamin D-replete women.

In conclusions undiagnosed vitamin D deficiency is frequent even among patients on pharmacological treatment for osteoporosis. Vitamin D deficiency is associated with the complete abolition of the benefits expected from osteoporosis therapy and is also likely to be associated with an increased risk for a number of severe conditions such as falls, cancer, cardiovascular diseases and cognitive impairment (Holick et al, 2007). It is highly recommended that all patients are checked for vitamin D deficiency before commencing any pharmacological treatment for osteoporosis. If the 25OHD levels are low, a personalized and continuous dose should be considered, avoiding the loading doses.

Table 1.

Definition	25 OH vitamin D	Manifestations - Comments
Vitamin D deficiency	< 10 ng/ml (25 nmol/l)	Osteomalacia (mineralization defect), muscle weakness
Vitamin D insufficiency	< 20 (50 nmol/l)	Secondary hyperparathyroidism, osteoporosis, increased morbidity
Vitamin D adequacy	20-30 ng/ml (50 to 75 nmol/l)	Bone turnover and PTH normalized
	≥ 30 ng/ml (75 nmol/l)	Desirable target in the fragile elderly due to optimal benefits on fracture, falls and mortality
Upper limit of adequacy	> 80 ng/ml (200 nmol/l)	Possible adverse effects above this level (Hypercalcaemia, hypercalciuria)
Maximum safe dose	2000 IU/day	Higher toxicity in patients with granulomatosis
Increases per 100 IU/day of vitamin D	1,2 ng/ml	Greater changes in vitamin D repleted subjects

IN-DEPTH DISCUSSION II

Atypical femoral fractures in patients on antiresorptive therapy

Bisphosphonates and denosumab decrease the risk of fracture in postmenopausal osteoporosis. Nevertheless, reports of femoral shaft fractures in primarily postmenopausal women treated for long periods of time with alendronate generated the definition of “atypical femoral fractures” (AFFs). These were suggested as a possible clinical manifestation of the old and unproven “frozen bone” concept, in which treatment-induced suppression of bone turnover would lead to decrease bone strength.

The first nine reported cases of spontaneous non-vertebral fractures in alendronate-treated patients, including 3 diaphyseal femoral fractures, were characterized by delayed or absent healing and bone turnover inhibition with no double labelling on histomorphometry, suggesting a treatment effect that was either too strong or too long lasting (Odvina et al, 2005). A systematic analysis of 141 published cases (Giusti et al, 2010) showed that the link between bisphosphonate exposure, bone turnover suppression and atypical femoral fractures occurrence was not as clear as suggested initially. First, the histomorphometry findings do not clearly support treatment-induced bone turnover inhibition as the only mechanism underlying atypical femoral fractures. A decrease in bone formation was not found in all cases. This decrease was marked in some patients but was not accompanied with mineralization disorders, and increased resorption was observed occasionally (Somford et al, 2009; Giusti et al, 2010; Shane et al, 2014). In addition, atypical femoral fractures occurred after less than 3 years of bisphosphonate exposure in 25% of cases (median of 60 months, range of 3 to 192 months) (Giusti et al, 2010), which does not support a role for excessively prolonged bone turnover inhibition. However, recent retrospective data indicate that longer duration of treatment with bisphosphonates results in augmented risk of atypical fractures (Meier et al, 2012). Moreover, atypical femoral fractures are also observed in patients treated with denosumab, and in bisphosphonate and denosumab-naïve patients (Meier et al, 2012), adding further complexity to the understanding of the pathogenesis.

The reported cases have allowed the identification of several distinctive features of atypical femoral fractures (Lenart et al, 2005). A task force of the American Society for Bone and Mineral Research (ASBMR) defined diagnostic criteria, revised in 2013, to improve the recognition and incidence assessment of atypical femoral fractures (Table 1) (Shane et al, 2014). AFFs are characterized by unique radiographic and clinical features (prodromal pain, bilaterality) that resemble stress fractures or reactions (figure 1 and 2).

Epidemiological data support a relationship between bisphosphonates use and atypical subtrochanteric and femoral shaft fractures (Abrahamsen et al, 2009; Abrahamsen et al, 2010; Schilcher et al, 2011). AFFs appear to be more common in patients who have been exposed to long-term bisphosphonates, usually for more than 3 years, even if AFFs have been reported in patients treated by denosumab, or patients who have never been treated with antiresorptive drugs. The risk for AFFs may decline after bisphosphonates are stopped (Schilcher et al, 2011). The majority of studies have found a significant association with glucocorticoids or proton pump inhibitors use or duration. Although the relative risks of AFFs are very high in patients on BPs, ranging from 2.1 to 128, their absolute risk is extremely low, ranging from 3.2 to 50 cases per 100,000 person-years.

Table 1: Diagnostic criteria for atypical femoral fractures (ASBMR Task Force 2013 Revised Case Definition of AFFs) (Shane et al, 2014).

To satisfy the case definition of AFF, the fracture must be located along the femoral diaphysis from just distal to the lesser trochanter to just proximal to the supracondylar flare. In addition, at least four of five Major Features must be present. None of the Minor Features is required but have sometimes been associated with these fractures.

Major features

- The fracture is associated with minimal or no trauma, as in a fall from a standing height or less
- The fracture line originates at the lateral cortex and is substantially transverse in its orientation, although it may become oblique as it progresses medially across the femur
- Complete fractures extend through both cortices and may be associated with a medial spike; incomplete fractures involve only the lateral cortex
- The fracture is non-comminuted or minimally comminuted
- Localized periosteal or endosteal thickening of the lateral cortex is present at the fracture site (“beaking” or “flaring”)

Minor features

- Generalized increase in cortical thickness of the femoral diaphyses
- Unilateral or bilateral prodromal symptoms such as dull or aching pain in the groin or thigh
- Bilateral incomplete or complete femoral diaphysis fractures
- Delayed fracture healing

Exclusion criteria

- fractures of the femoral neck, intertrochanteric fractures with spiral subtrochanteric extension, periprosthetic fractures, and pathological fractures associated with primary or metastatic bone tumours and miscellaneous bone diseases (e.g., Paget’s disease, fibrous dysplasia).

These fractures are now considered as stress or insufficiency fractures which do not normally heal. The suppression by anti-resorptive therapy of intracortical remodelling at the site of the stress fracture would impair the processes by which stress fractures normally heal, potentially including microdamage accumulation and changes to bone mineralisation and collagen crosslinking, which can progress to full fracture. The location of AFFs at the subtrochanteric and femoral shaft regions is probably related to mechanical forces on the lower limb, which may be influenced by the geometry of the hip and proximal femur. Hip geometry determines in part the stresses that are experienced on the lateral aspect of the femoral cortex. The lateral cortex of the femur is known to sustain high levels of tensile stress due to bending which may precipitate the damage in this location especially in those people with lower limb geometry that could exacerbate that effect (e.g., a bowed femur, Asian race).

Regarding clinical prodromal symptoms, a complaint of thigh pain from a patient at risk for osteoporosis should suggest this possibility, particularly if the patient has a history of bisphosphonate exposure. The time

interval from the onset of prodromic pain and the diagnosis of an atypical femoral fracture varies widely, from 1 week to 2 years (Giusti et al, 2010). Any thigh pain in a BP-treated patient should lead to the immediate interruption of the treatment and appropriate diagnosis procedure. Incomplete AFF may be observed on X-ray in this context before the complete fracture occurs (Figure 2). The index of suspicion should be particularly high in patients with rheumatoid arthritis, chronic obstructive pulmonary disease, asthma, or diabetes; and in those with a history of exposure to systemic glucocorticoid therapy or proton pump inhibitors. Recurrences have been reported in patients who had several of these risk factors (Giusti et al, 2010).

Bone scintigraphy combined with single photon emission CT (SPECT) or MRI can assist in the early diagnosis of bone fragility heralding a fracture, consistent with a stress fracture (Somford et al, 2009), which should be considered if clinical suspicion for AFF remains high despite normal plain radiographs. In contrast, it seems that neither bone marker levels (Shane et al, 2014) nor bone mineral density values (Giusti et al, 2010) are of diagnostic assistance.

Where an atypical femoral fracture is diagnosed, the ASBMR recommend discontinuing the bisphosphonate, optimising calcium and vitamin D status, and to consider teriparatide. It is still unclear if teriparatide may advance healing of AFFs with no available randomised studies, but there are an increasing number of case reports of its beneficial impact on healing as an adjuvant. Its use has been considered due to improved bone turnover and microarchitecture in patients on long term alendronate - with enhanced fracture healing by increased callus formation and mechanical strength – together with two clinical trials showing shortened healing time in patients with osteoporotic fractures (Kharwadkar et al 2017). Intramedullary nailing should be considered for complete AFF or painful incomplete AFF. If asymptomatic incomplete AFF, then minimal weightbearing until MRI shows no bone oedema with MRI surveillance is suggested. The UK MHRA recommends imaging the contralateral side if an AFF is found as they can occur bilaterally.

Although both the existence of atypical femoral fractures and the major role for bisphosphonate therapy as a risk factor have been firmly established, these fractures account for only a small proportion of subtrochanteric and diaphyseal femoral fractures. Therefore, the risk of atypical femoral fractures does not call into question the favourable risk/benefit ratio of antiresorptive drugs in patients with osteoporosis at high risk of fracture. Together with recent data on the effect of bisphosphonate duration on fracture risk reduction, these AFFs contribute, in clinical practice, to limit currently bisphosphonate duration to 3 to 5 continuous years.

1 PAGET'S DISEASE OF BONE

LEARNING OBJECTIVES

- Determine the epidemiology and main genetic factors involved in Paget's disease
- Make the diagnosis of Paget's disease based on clinical evaluation, imaging and biology testing
- Manage and monitor treatment

1.1 Introduction

Paget's disease of bone (PDB) is a chronic benign condition characterised by focal areas of increased and disorganised bone remodelling affecting various sites throughout the skeleton. The disease mostly involves the axial skeleton, and bones that are commonly affected include the pelvis, femur, tibia, lumbar spine, skull and scapula. The condition can be monostotic (i.e., affecting one bone only) or polyostotic (i.e., involving several bones).

1.2 Epidemiology

Paget's disease is seldom diagnosed before the age of 40 but gradually increases in incidence thereafter to affect up to 10% of the UK population by the age of 85. PDB affects both genders, with apparently a small male predominance. Incident disease activity decreases with age and no impact on survival has been observed in a US population (Wermers et al, 2008). The disease is common in Caucasian populations from north-west and southern Europe but is rare in Scandinavian, Asian, Chinese and Japanese populations. This ethnic susceptibility persists after migration in particular in Caucasians, illustrating the importance of genetic factors in aetiology. According to a recent meta-analysis, the incidence of PDB has also been found to have decreased in some countries over the past 25 years (Corral-Gudino et al, 2013), suggesting that environmental factors also play a role. This decrease in the prevalence of PDB has not been observed in Spain and Italy, nor in Asian descents living in New Zealand (Sankaran et al, 2012). It should be recalled that part of the appearing decrease in prevalence could be attributed to the evolution in radiological techniques. Indeed, plain abdomen X rays, intravenous pyelography or barium colonic enema that were used in initial epidemiologic studies to determine the PDB frequency, are nowadays much less utilized than ultrasonography and endoscopic examinations which are unable to study the skeleton. What seems to have been observed more recently is a decrease in the severity of PDB and changes in the mode of presentation of PDB (Tan et al, 2014).

1.3 Pathogenesis

Pagetic bone lesions show evidence of focal increased osteoclastic bone resorption which is accompanied by other abnormalities such as marrow fibrosis, increased vascularity of bone and increased bone formation (Galson et al, 2014*). The rapid rate of bone turnover in PDB leads to the production of woven bone which has reduced mechanical strength, leaving patients at increased risk of developing deformities and pathological fractures. Osteoclasts are increased in number and size and contain nuclear inclusion bodies, which are micro-cylindrical structures that resemble virus particles. These inclusion bodies are not specific for PDB, however, and their true identity has not yet been established. The discovery of these particles led to the suggestion that PDB may be due to a persistent measles viral infection of bone cells, although data on this are conflicting. Interestingly, osteoblasts are also abnormal in PDB. They are produced in greater numbers, and they form more bone for a longer time than normal osteoblasts. Also, they overexpress cytokines such as IL-6 and Dickkopf-1, an antagonist of the Wnt/ β -catenin signalling pathway.

The cause of PDB is incompletely understood, but genetic factors clearly play an important role (Galson et al, 2014*). Approximately 15% of PDB patients have a positive family history and the risk of developing PDB is increased seven- to tenfold in the first degree relatives. In several families, classic PDB is inherited as an autosomal dominant trait with high penetrance. In the recent years, several genetic variations have been identified in genes associated with PDB and related syndromes. The most important gene linked to classic PDB is sequestosome 1 (SQSTM1) which encodes p62, a scaffold protein that is involved in NF- κ B signalling (Hocking et al, 2012). Missense and stop mutations of SQSTM1, almost all located in the region coding the ubiquitin binding domain of the SQSTM1/p62 protein, have been reported to account for 20–50% of cases of familial PDB and 8–20% of cases of sporadic PDB. Some evidence suggests that loss of ubiquitin binding is one mechanism by which SQSTM1 mutations causes PDB, although autophagy may also be involved (Hocking et al, 2012). Patients with SQSTM1 mutations have severe PDB and penetrance is between 80% and 100% by the seventh decade. It is likely that environmental factors interact with SQSTM1 mutations to affect disease severity since a recent study showed that children of SQSTM1 mutation carriers resident in New Zealand had a 5–10-year delay in onset of the disease compared with their parents. In approximately 60% of patients with classic PDB, the gene is unknown but candidate loci for susceptibility genes have been discovered on chromosomes 5q31 and 10p13. Recent genome-wide association studies have identified polymorphisms that are associated with the disease: TNFRSF11A, which encodes the receptor activator of NF- κ B, colony stimulating factor-1 and optineurin (Albagha et al, 2010), as well as TM7SF4, encoding DC-STAMP, RIN3, NUP205, and PML (Albagha et al, 2011).

The pathogenetic role of environmental factors, classically associated with PDB according to the literature, such as deficiencies in calcium or vitamin D during childhood, biomechanical stress from repetitive use of affected bones, environmental exposure to combustion products, rural lifestyle, domestic animal exposure,

and chronic infection with the paramyxoviruses such as measles virus, canine distemper virus, and respiratory syncytial virus (Galson et al, 2014*) still remains unclear.

1.4 Clinical features

The most common presentation of PDB nowadays is through incidental finding of elevated serum alkaline phosphatase (ALP) or an abnormal X-ray that is performed for another clinical indication. Occasionally, PDB presents with specific features such as bone pain and deformity. Bone pain due to PDB is typically present at rest and at night as well as upon using an affected limb. In clinical practice, however, it is often difficult to distinguish pain secondary to the increased metabolic activity of PDB from pain due to secondary osteoarthritis or unrelated conditions such as degenerative disc disease. Bone deformity is a feature of advanced PDB (figure 1). Patients with metabolically active disease may exhibit an increase in the skin temperature over affected bones, explained by hypervascularity. This sign is usually most apparent in patients with PDB of the tibia or the patella. Paget's disease can be associated with several complications including deafness, pathological fracture, secondary osteoarthritis, cranial nerve compression syndromes and spinal stenosis (box 1) and the disease has a significant negative impact on quality of life (Langston et al, 2007). Although these conditions are common in elderly patients without PDB, epidemiological studies have shown that Paget's patients are three times more likely to need a hip replacement for osteoarthritis compared with age-matched controls and nearly twice as likely to need a knee replacement (van Staa et al, 2002). Other complications that are significantly more common in Paget's disease when compared with controls include hearing loss, tinnitus, dizziness, back pain, osteoarthritis and fracture. Partial fissure fractures can be observed perpendicular to the outer cortex of bowed bones. They can prolong to complete transverse atypical fractures. Paraplegia is a rare complication. This can occur as the result of spinal cord compression to bony expansion of affected vertebrae but can also occur as the result of a vascular steal phenomenon due to increased blood flow in affected vertebrae. Osteosarcoma is a rare complication of PDB, occurring in about 0.1% of patients, but most osteosarcomas that occur in adulthood are associated with PDB (van Staa et al, 2002). Patients with PDB who are immobilised can develop hypercalciuria and hypercalcaemia. The most common scenario is the result of dehydration when an affected patient is confined to bed because of an intercurrent illness or following surgery. High output cardiac failure has been described due to increased blood flow through affected bone but is extremely rare.

Figure 1. Bone deformity of the tibia in Paget's disease

Box 1. Complications of Paget's disease of bone.

Common
• Bone pain
• Bone deformity
• Pathological fracture
• Osteoarthritis
• Deafness
Less Common
• Spinal stenosis
• Nerve compression syndromes
Rare
• Hypercalcaemia (with immobilisation)
• Hydrocephalus
• Paraplegia
• Cardiac failure
• Osteosarcoma

1.5 Diagnosis

The diagnosis of PDB is usually made on the basis of X-ray, biochemical screening and radionuclide bone scans. The typical biochemical abnormality in active PDB is an elevated ALP level in the presence of otherwise normal biochemistry, including Gamma-glutamyl transferase. Levels of ALP are elevated in over 90% of cases but can be normal when only a single bone is affected. Other specialised biochemical markers such as the urine deoxypyridinoline/creatinine ratio, bone specific ALP and the amino-terminal propeptide of type I collagen

(P1NP) are also elevated in active PDB, but in routine practice their evaluation does not seem to offer much advantage over ALP in the assessment of patients. A radionuclide bone scan is a useful way of screening for the presence of PDB and documenting its extent (figure 2). If the bone scan is positive, radiographs should be performed on all affected bones to confirm the diagnosis. Typical features on X-ray are osteosclerosis, alternating with osteolysis, bone expansion and bone deformity (figures 3–7). Bone biopsy is not usually required to make the diagnosis of PDB, but it can be helpful when the diagnosis is not clear and specifically to differentiate PDB from osteosclerotic metastases, particularly in prostate cancer bone metastases that can co-exist with PDB in the same patient. In rare cases, giant cell tumours can develop, particularly in very extensive PDB (figure 8A–C) (Rendina *et al*, 2015). Increase in pain intensity, pain at night, occurrence of a biological inflammatory syndrome and/or hypercalcemia without a context of immobilization can be considered as red flags for malignant degeneration of pagetic bone (figure 9).

Figure 2. Bone scan in Paget's disease

a. Radionuclide scan showing increased tracer uptake in the pelvis, both femurs, lumbar spine, scapula, sternum and base of the skull, typical of PDB at these sites.

b. Other patient with uptake in the left tibia and both femurs. Personal collection of Prof P Orcel, Rheumatology, Lariboisière Hospital, Paris, France.

Figure 3. X-ray appearances in Paget's disease. X-rays of the tibias (lateral view) show alternating areas of osteosclerosis and osteolysis and expansion of the bone. (Same patient as in Figure 2b). Personal collection of Prof P Orcel, Rheumatology, Lariboisière Hospital, Paris, France.

Figure 4. Involvement of the skull. X-ray of the skull from a patient with PDB showing circumscribed osteolytic skull lesion. Personal collection of Prof P Orcel, Rheumatology, Lariboisière Hospital, Paris, France.

Figure 5. Secondary osteoarthritis in PDB. Typical PDB radiographic signs with bilateral secondary osteoarthritis of the hips. Personal collection of Prof P Orcel, Rheumatology, Lariboisière Hospital, Paris, France.

Figure 6 a, b and c. Monostotic vertebral Paget's disease in the lumbar vertebra L4 with secondary spinal stenosis, in a female patient aged 82 years (CT-scan, sagittal views). Diagnosis was made at 58 years. Patient was treated with IV bisphosphonates. Personal collection of Prof JP Devogelaer, Rheumatology, Cliniques Universitaires Saint - Luc, Brussels, Belgium.

Figure 8. Giant cell tumour in a Pagetic site at the humerus, in a polyostotic Paget disease in a male patient aged 31. Personal collection of Prof JP Devogelaer, Rheumatology, Cliniques Universitaires Saint - Luc, Brussels, Belgium.

a. Radionuclide scan showing increased tracer uptake at several sites in polyostotic PDB

b, c. Giant cell tumour in a Pagetic site at the humerus in the same patient (X-ray, MRI t1 weighted coronal image)

Figure 9 a, b and c. Osteosarcoma complicating Paget's disease of the right pelvis and sacrum in a 75 years old patient with PDB and persistent bone pain at night, even after right hip replacement. Typical aspects of heterogeneous bone lesion with severe osteolysis and blastic lesions on radiographs, CT-scan and heterogeneous hypermetabolism on FDG-PET scan.

1.6 Medical Management

The main indication for treatment of PDB is pain, which may arise from an increase in metabolic activity, from bone deformity, from nerve compression syndromes, from secondary osteoarthritis or from co-existing diseases. In many cases, pain can be adequately controlled by administration of painkillers such as paracetamol or non-steroidal anti-inflammatory drugs, but if these measures are ineffective, then bisphosphonates should be given (table 1). Bisphosphonates are generally effective at controlling pain from the increased metabolic activity of PDB, but are generally less effective at treating pain which occurs as the result of complications such as deformity, nerve compression syndromes or secondary osteoarthritis. Aminobisphosphonates such as pamidronate, risedronate, alendronate and zoledronic acid are more effective than older bisphosphonates such as etidronate and tiludronate at suppressing biochemical markers of bone turnover in PDB. However, randomised comparative studies of different bisphosphonates have generally shown no significant difference between therapies in terms of pain control (Langston and Ralston, 2004*) except from recent comparative study of risedronate versus zoledronic acid where zoledronic acid was shown to be slightly superior to risedronate in treating bone pain (Reid et al, 2005). The advantages of zoledronic acid are mainly its easy mode of administration and its long-lasting efficacy (Devogelaer et al, 2014), a single infusion being able to induce a disease suppression in two-third of patients (Cundy et al, 2017). Calcitonin can be used as an alternative to bisphosphonate therapy in PDB, but is less convenient to administer and

significantly more expensive. It should be reserved for the rare cases of intolerance to bisphosphonates. There is no longer any indication for etidronate in PDB therapy.

Table 2. Bisphosphonates used in the treatment of Paget's disease

Drug	Trade Name	Dose
Clodronate	Loron, Bonefos	400–1600 mg/day orally for 3–6 months or 300 mg/day intravenously for 5 days
Pamidronate	Aredia	60 mg/day intravenously for 3 days
Alendronate	Fosamax	40 mg/day for 6 months
Tiludronate	Skelid	400 mg/day for 3 months
Risedronate	Actonel	30 mg/day for 2 months
Zoledronic acid	Aclasta/Reclast	5 mg intravenously by a single injection

The long term effects of anti-resorptive therapy with bisphosphonates and calcitonin on complications of PDB such as deafness, bone deformity and fracture are unknown since most studies were on short term follow-up and have focused on biochemical markers as the primary endpoint.

1.7 Surgical Management

Surgery is frequently required for the management of complications. The most common indication for surgical treatment is arthroplasty for osteoarthritis, but surgery may also be required for fracture fixation, osteotomy to correct bone deformity, and surgery to correct spinal stenosis. Surgery in patients with PDB can be technically challenging because of bony enlargement, deformity and increased vascularity, although in general, the results of surgery in PDB are favourable and significantly improve the quality of life for patients with the condition, particularly those with advanced osteoarthritis. Bisphosphonate therapy is frequently given before elective orthopaedic surgery in the hope that this might reduce operative blood loss. The effects of bisphosphonate therapy on blood loss have never been studied in a controlled trial but this approach is widely recommended by experts (Singer et al, 2014). Orthopaedic surgery may also be required for the treatment of osteosarcoma, but the prognosis is poor even with aggressive operative treatment.

1.8 Monitoring disease activity

Serum alkaline phosphatase (total ALP) levels are generally used to assess the activity of PDB and to monitor the effects of anti-resorptive treatment. Other specialised markers of bone turnover are marginally more sensitive, but costs are greater and there is no evidence that, beyond the context of monostotic PDB, they offer any clinical benefit over ALP. Some clinicians give anti-resorptive therapy routinely when ALP levels are raised (by $\geq 25\%$ compared to the lowest total ALP level) and aim to maintain levels within the lower half of the normal range by repeated courses of anti-resorptive therapy (Singer et al, 2014). After a first successful course

of therapy, ALP should be measured every 6–12 months in order to identify any recurrence of the condition. Other clinicians provide treatment when patients experience symptoms related to Paget's disease. These strategies seem to provide equivalent results in established PDB; in a recent study, no clinical benefit was observed in patients who received repeated courses of bisphosphonate with the aim of maintaining normal levels of ALP as compared with those given symptomatic treatment for bone pain. This randomised trial showed no significant differences between groups in quality of life, bodily pain, Pagetic bone pain, clinical fractures or orthopaedic surgery (Langston *et al*, 2010). Currently, there is no evidence to show that prophylactic therapy with bisphosphonates is effective at preventing complications of Paget's disease. Experts recommend the repeat of x-rays in the follow-up of osteolytic lesions after one year, in case of persistent elevation of bone markers and persistence of bone pain (Singer *et al*, 2014).

2 OSTEOMALACIA

LEARNING OBJECTIVES

- ➔ List the main causes of osteomalacia

2.1 Definition

Osteomalacia is the term used to describe a syndrome of defective bone mineralisation, bone pain, increased bone fragility and fractures that occurs in adults. Osteomalacia is considerably less common nowadays due to improved nutrition and sunlight exposure. However, the disease remains prevalent in elderly and housebound patients who have a poor diet, limited sunlight exposure and in Moslem women who live in northern latitudes. The most common cause of osteomalacia is vitamin D deficiency, but many pathological states can lead to osteomalacia including tumours and drugs.

2.2 Vitamin D deficiency and osteomalacia

The most common cause of osteomalacia is reduced sunlight exposure since ultraviolet light stimulates conversion of 7-dehydrocholesterol in the skin to cholecalciferol. Cholecalciferol then undergoes 25-hydroxylation in the liver to produce $25(\text{OH})\text{D}_3$ which is converted into the active metabolite $1,25(\text{OH})_2\text{D}_3$ by the kidney. Osteomalacia can also occur as the result of reduced dietary intake, as vitamin D concentration is usually low in most foods, except in oily fish, so the amount present in the average diet is generally insufficient to meet requirements.

In the presence of vitamin D deficiency, production of $1,25(\text{OH})_2\text{D}_3$ is therefore reduced. This results in impairment of intestinal calcium absorption with reduced influx of calcium from the gut into the blood. This tends to lower serum ionised calcium which is detected by the parathyroid gland, causing increased secretion of parathyroid hormone (PTH). This secondary hyperparathyroidism leads to renal phosphate wasting and increased bone turnover. While the elevation in PTH is usually sufficient to maintain serum calcium levels within the normal range, in the early phase of the disease, this is at the expense of progressive demineralisation of bone and increased fracture risk. Low vitamin D, calcium and high PTH thus contribute to the bone defects.

2. 3 Other causes of osteomalacia

Aluminium intoxication can cause osteomalacia in patients with chronic renal failure due to direct inhibition of mineralisation (Boyce et al, 1982). The condition is now rare due to a reduction in the use of aluminium-containing phosphate binders and removal of aluminium from water supplies used in dialysis. The diagnosis can be confirmed by demonstration of aluminium accumulation in an iliac crest biopsy specimen.

Bisphosphonates can cause osteomalacia due to direct inhibition of mineralisation. This has mostly been described in patients with Paget's disease receiving etidronate and high dose pamidronate (Boyce et al, 1984; Boyce et al, 1994). In most cases the osteomalacia is asymptomatic and healing occurs when treatment is stopped. Excessive intake of fluoride also causes osteomalacia due to direct inhibition of mineralisation and is common in region where there is a high fluoride content in drinking water. The condition is reversible when fluoride intake is reduced. A rare cause of osteomalacia is tumour-induced osteomalacia (mesenchymal tumours). The presentation resembles vitamin D-deficient osteomalacia, but serum phosphate levels are low due to increased urinary phosphate excretion. The syndrome is caused by over-production of FGF23 by the tumour. FGF23 acts directly on the proximal tubule to inhibit renal phosphate reabsorption (Shimada et al, 2001; Quarles, 2012). The mesenchymal tumour producing FGF23 can be localized by octreotide scan (figure 4). Treatments include supplementation with active vitamin D and phosphate but definitive cure is only possible by removal of the tumour.

Finally, drugs used in the treatment of AIDS can provoke hypophosphatemic osteomalacia, notably the association tenofovir/emtricitabine. Serum phosphate level should always be measured in AIDS patients before initiation of therapy as well as every 6 months during treatment.

The main causes of osteomalacia are summarised in box 1.

Box 1. Non-exhaustive causes of osteomalacia**Shortage in vitamin D or vitamin D action**

- Dietary deficiency
- Malabsorption (small intestinal diseases, gastrectomy, hepatobiliary disease, pancreatic insufficiency)
- Deficient endogenous synthesis
 - Acquired: hepatic or renal insufficiency, hypoparathyroidism
 - Hereditary: Pseudo vitamin D deficiency type I (autosomic recessive transmission), due to a mutation in the gene coding for the P450 cytochrome in the 25(OH)D-1 α -hydroxylase enzymatic complex, implicated in 1,25-dihydroxy-vitamin D production in the kidney
- Renal loss (nephrotic syndrome)
- Excessive catabolism (chronic intake of anticonvulsants)
- Deficient action due to vitamin D receptor mutation
 - Pseudo vitamin D deficiency type II (autosomic recessive transmission)

Shortage in calcium

- Dietary deficiency (daily intake < 200 mg/d, parenteral nutrition)
- Malabsorption (small intestinal diseases, vitamin D shortage)

Shortage in Phosphate

- Dietary deficiency (i.e. parenteral nutrition)
- Malabsorption (low phosphate intake associated with ingestion of non-absorbable antacids)
- Renal loss due to impaired renal phosphate reabsorption:
 - Proximal tubulopathy (complete or incomplete Fanconi's syndromes)
 - primary renal (phosphate diabetes)
 - intoxications (i.e. cadmium, lead, iphosphamide, tetracycline, HIV treatment)
 - metabolic abnormalities (i.e. cystinose, glycogenose, tyrosinose, Wilson's disease, fructose intolerance...)
 - multiple myeloma, nephrotic syndrome, transplanted kidney
 - neurofibromatosis, fibrous dysplasia
- Excess of phosphatonines: excess of FGF-23 (i.e. tumour-induced osteomalacia)

Defect in bone mineralization

- Enzymatic deficiency (hypophosphatasia)
- Intoxications (Aluminium, Fluoride, first generation bisphosphonates, i.e. etidronate, high dose of pamidronate)

2.4 Clinical features

Clinical presentation of steomalacia is usually insidious. Mild osteomalacia can be asymptomatic or presents with fractures and mimic osteoporosis. More severe osteomalacia presents with muscle and bone pain, general malaise and fragility fractures. Proximal muscle weakness is prominent and the patient may walk with a waddling gait and experience difficulty in climbing stairs or getting out of a chair. There is bone and muscle tenderness on pressure. Focal bone pain may occur in association with fractures of the feet, ribs and pelvis.

Osteomalacia due to phosphate diabetes can be complicated by spinal stenosis due to ossification of intervertebral ligaments, which is the posterior longitudinal ligament, the ligamenta flava (figures 1 and 2) (Velan *et al*, 2001).

2.5 Investigations

In most cases the diagnosis can be made or strongly suspected on the basis of a routine biochemical screen with measurement of serum 25(OH)D, calcium, phosphate, and PTH. Typically, serum alkaline phosphatase levels are increased, 25(OH)D levels are low or undetectable and PTH is raised. Serum calcium and phosphate levels may also be low, but normal values do not exclude the diagnosis. The bone remodelling is increased, and parameters of bone turnover such as alkaline phosphatase activity (total and bone-specific), C-telopeptide (CTx) and PINP are elevated. In tumour-induced osteomalacia, phosphatonins such as FGF23 levels are high. A careful review of the patients' medications (that can cause osteomalacia) should be performed.

Radiographic examination is not generally helpful and is normal until advanced disease where focal radiolucent areas (pseudo-fractures or Looser's zones) may be seen in the ribs, pelvis and long bones (figure 3). Radiographic osteopenia is common and the presence of vertebral crush fractures may cause confusion with osteoporosis. In children, there is thickening and widening of the epiphyseal plate. Radio-nuclide bone scans can show multiple hot spots in the ribs and pelvis at the site of fractures and sometimes the appearance is mistaken for metastatic disease. In cases where there is any doubt, the diagnosis can be confirmed or excluded by iliac crest biopsy, which shows the pathognomonic features of increased thickness and extent of osteoid seams (non-mineralized bone).

2.6 Management and treatment

Osteomalacia responds rapidly and fully to treatment with ergocalciferol (vitamin D2) or cholecalciferol (vitamin D3) (250 µg or 10 000 IU daily). This results in normalization of 25(OH)D and a reduction in PTH levels. Serum alkaline phosphatase levels sometimes rise initially as mineralisation of bone increases, but eventually returns to normal values as the bone disease heals. After 3 to 4 months of treatment, the dose of vitamin D is reduced to a maintenance level of 20 µg or 800 IU cholecalciferol daily, except in patients with underlying disease such as malabsorption, where higher doses may be required.. In tumour-induced osteomalacia, removal of the tumour (if possible) should be performed.

Figure 1. Spinal stenosis provoked by ossification of the posterior longitudinal ligament at C2, C3 levels, as seen on X-ray films and on MRI, in the same male patient aged 49 years. Personal collection of Prof JP Devogelaer, Rheumatology, Cliniques Universitaires Saint - Luc, Brussels, Belgium.

Figure 2. Severe spinal stenosis provoked by ossification of the ligamenta flava at dorsal level, in a female patient aged 56 years. Personal collection of Prof JP Devogelaer, Rheumatology, Cliniques Universitaires Saint - Luc, Brussels, Belgium.

Figure 3. Looser's zones of both femoral necks in a 56 years old man with tumour-induced osteomalacia.

Figure 4. Tumour-induced osteomalacia. Localization of the tumour at the right sole by octreotide scan (same patient than in figure 3).

SUMMARY POINTS

- ➡ Osteomalacia due to vitamin D deficiency can induce muscle weakness, bone pain and fracture.
- ➡ Biological diagnosis relies on a low level of 25(OH)D and increased serum alkaline phosphatase.
- ➡ Treatment is based on ergocalciferol or cholecalciferol.
- ➡ Osteomalacia can also be caused by aluminium intoxication, excess fluoride or overproduction of FGF23.

3 RENAL OSTEODYSTROPHY**LEARNING OBJECTIVES**

- ➡ Explain the pathophysiology of renal osteodystrophy
- ➡ Classify the different forms of renal osteodystrophy

3.1 Introduction and pathophysiology

Renal osteodystrophy (ROD) is defined by the bone anomalies that occur in patients with chronic kidney (CKD) disease. It is a part of a syndrome called CKD-MBD (chronic kidney disease-mineral and bone disorders) that also includes biochemical anomalies and vascular calcification (Mac-Wee et al, 2012). In CKD, there is inability of the failing kidneys to hydroxylate 25-hydroxyvitamin D3 to 1,25-dihydroxyvitamin D3 (the active form of vitamin D) and to excrete phosphate. Reduced production of 1,25-dihydroxyvitamin D3 causes reduced intestinal calcium absorption leading to mild hypocalcaemia while hyperphosphatemia contributes to the increased prevalence of vascular and soft tissue calcifications in CKD patients to compensate for these changes, secondary hyperparathyroidism develops with hyperplasia of the parathyroid glands and increased FGF23 from the bone. The progressive lowering of 1,25-dihydroxyvitamin D3 furthermore changes the 'set point' of the parathyroid glands, leading to a higher level of serum parathyroid hormone (PTH) than expected for a given serum concentration of calcium. In addition, there is evidence at the tissue level of downregulation of vitamin D receptor and resistance to the action of PTH. Unfortunately, kidney fails to respond adequately to PTH and FGF23, which normally promote phosphaturia and calcium reabsorption so that PTH and FGF23 are chronically elevated and deleterious for the bone. Recently, anomalies of osteocytes (bone cells), through sclerostin secretion, have been suggested to be involved in the pathophysiology of ROD. Therefore, anomalies of calcium, phosphate, vitamin D, PTH and FGF23 all contribute to the anomalies of bone in CKD patients.

Further contributors to bone disease are age, immobilisation, glucocorticoid treatment, diabetes mellitus, postmenopausal osteoporosis and aluminium intoxication. The latter problem was common two decades ago, but control of the concentration of aluminium in dialysis water and cessation of the use of aluminium-containing phosphate binders have dramatically reduced the prevalence of the condition.

The mineral and biochemical anomalies that occur in CKD are defined according to the patient's glomerular filtration rate (GFR) in order to highlight mineral and bone disorders (table 1).

Table 1. Stages of chronic kidney disease

Stage	Description	GFR (ml/min/1.73 cm ²)
1	Slight kidney damage with normal or increased filtration	≥ 90
2	Mild decrease in kidney function	60-89
3	Moderate decrease in kidney function	30-59
4	Severe decrease in kidney function	15-29
5	Kidney failure	< 15 or dialysis

If there are no biochemical anomalies (in PTH, calcium, phosphate, FGF23) suggesting ROD, osteoporosis can be diagnosed by dual energy X-ray absorptiometry if the T score is ≤−2.5 and/or if the patient has already experienced a fragility fracture (Miller, 2005). In patients where serum mineral metabolism is already abnormal or if GFR is <15 or under dialysis, a biochemical profile cannot easily distinguish between the various types of bone disease seen in CKD (see below). An iliac crest bone biopsy is thus needed to differentiate ROD from osteoporosis and in order to propose adapted treatment.

3.2 Different forms of ROD

The gold standard for the classification of ROD is bone histomorphometry with double tetracycline labelling from iliac crest biopsy. According to the extent of osteoid (unmineralised bone) and bone turnover (the bone formation rate evaluated by the double tetracycline labelling), four different types have been described: osteitis fibrosa (secondary hyperparathyroidism), mixed form (secondary hyperparathyroidism + mineralisation defect), osteomalacia (classical mineralisation defect) and adynamic bone disease (ABD, figure 1). The distribution of these histological types differs between studies, which may not reflect reality and might be due to the fact that only symptomatic patients have bone biopsies. Osteomalacia is actually extremely rare and was previously mainly the consequence of aluminium overload. Most patients with CKD have some degree of mineralisation defect corresponding to the mixed form. They present with evidence of high bone turnover as a consequence of secondary hyperparathyroidism. ABD has a histomorphometric definition (low bone formation rate without mineralisation defect). Its pathogenesis is multi-factorial, but excessive suppression of

parathyroid hormone, that may be secondary to excessive treatment with calcium and active vitamin D supplements, is the main determinant of adynamic bone disease. Recent studies suggest that sclerostin, which is an inhibitor of bone formation, may be implicated in the development of ABD. Adynamic bone disease may affect 30% of patients with ROD. It can present with high serum calcium and extraskeletal calcifications because of the inability of the adynamic bone to incorporate calcium.

Figure 1 Different histomorphometric forms of renal osteodystrophy: iliac crest bone biopsy, undecalcified, stained with Masson Trichrome (×50). Mineralised bone is blue and osteoid is red. (A) Adynamic osteopathy: absence of thick osteoid and few bone cells along the bone surfaces. (B) Mixed form: eroded bone surfaces are associated with thick osteoid on some trabecular surfaces. (C) Osteomalacia: thick osteoid on most of the trabecular surfaces. (D) HPT II (osteitis fibrosa): trabecular surfaces are eroded by many osteoclasts, marrow fibrosis and absence of thick osteoid. This figure is from the personal collection of Professor MC de Vernejoul.

3.3 Clinical features and investigations

ROD can be asymptomatic, but bone pain, periarticular pain, arthralgia, skeletal deformities and muscle weakness occur in patients with severe forms of the disease. Recently, it has also been observed that fractures are two to four times more frequent among patients on dialysis than in an age- and sex-matched population with normal renal function (Alem *et al*, 2000). Finally, there has been increasing concern regarding extraskeletal (vascular, periarticular or subcutaneous) calcifications that may result from the deranged mineral and bone metabolism of chronic renal failure and from the therapies used to correct these abnormalities. Several cohorts have shown an association between disorders of mineral metabolism and fractures, cardiovascular disease and mortality. These studies have broadened the focus of ROD to include cardiovascular disease, which is the leading cause of death in patients with CKD.

Because bone biopsy is not easily available, patients are classified according to biochemical measurement of serum PTH and total or bone alkaline phosphatase levels that reflect bone turnover (Mac-Wee *et al*, 2012 *et* Urena *et al*, 1996). In the recent KDIGO recommendations, the PTH level should be kept between 2 to 9 times the upper level of the normal PTH range in patients on dialysis. A sustained lower level of PTH could reflect adynamic bone disease and a higher level secondary hyperparathyroidism. The target levels of PTH in stage 3 and 4 are unknown but progressive elevation should probably be corrected. Serum calcium should be kept within normal values. An increase in serum calcium suggests tertiary hyperparathyroidism (autonomous production of PTH). In addition, serum phosphorus should be monitored and controlled tightly as prolonged hyperphosphatemia will induce extraskeletal calcifications and is associated with increased mortality. Low levels of 25-hydroxy-vitamin D3 (25(OH)D) should be corrected in most patients on dialysis as it has been associated with increased mortality by an unknown mechanism. Finally, FGF23 increase has been extensively shown to be associated with cardiovascular mortality and renal outcomes in CKD so that every effort should be made to avoid its elevation (Kanaan *et al*, 2010; Isakova, 2012; Isakova, 2013).

3.4 Management of patients with ROD

Guidelines for patients with CKD and mineral metabolism anomalies have been reviewed recently (Kidney Disease: Improving Global Outcomes, 2017*). In order to maintain normal serum phosphorus and prevent secondary hyperparathyroidism, phosphate binders (lanthanum carbonate or sevelamer chloride) should be used in addition to phosphate diet restriction. If there is hypocalcaemia, calcium supplements can be an option. Since calcium supplements may be associated with vascular calcification, recent KDIGO recommended to limit the calcium intake in CKD patients.

Vitamin D supplementation with cholecalciferol may be required in CKD patients in order to obtain a 25(OH)D serum level >30 ng/mL.

In case of secondary hyperparathyroidism, 1 α vitamin D derivatives can be used to reduce the PTH level. However, they will also induce an increase in both serum calcium and phosphate levels and could therefore contribute to extraskeletal calcifications if the serum phosphate level is not controlled. If PTH levels remain elevated (> 9 times the upper level of normal range), parathyroidectomy or cinacalcet, a calcimimetic binding the calcium sensing receptor in the parathyroid glands should be proposed. Cinacalcet will induce a decrease in parathyroid hormone levels and consequently also a decrease in serum calcium and phosphorus levels, and therefore has the potential to decrease extraskeletal calcifications. Patients with severe hyperparathyroidism who fail to respond to this cinacalcet will require subtotal parathyroidectomy.

There is no medical treatment for adynamic bone disease. Excessive suppression of PTH by calcium and 1 α vitamin D derivatives should be avoided.

Finally, management of CKD patients with fracture are challenging. CKD patients without mineral anomalies should be treated as osteoporosis patients (Moe S, 2017). Otherwise, a CKD patient with high risk of fracture or with established fracture should be evaluated for an iliac crest biopsy in order to determine the level of bone turnover (KDIGO 2016). If this is not available, PTH and alkaline phosphatase should help. In patients with high bone turnover, anti-resorptive treatments such as bisphosphonate or denosumab can be used (Block *et al*, 2012). It is however important to control the biochemical anomalies that are typically seen in CKD before considering anti-resorptive. CKD patients with ABD may be treated with teriparatide but a bone biopsy is recommended in order to confirm the diagnosis.

SUMMARY POINTS

- ➔ Renal osteodystrophy defines the bone anomalies in CKD and is a reflect of calcium, phosphate, PTH, FGF23 and vitamin D abnormalities.
- ➔ A low level of PTH can induce adynamic bone disease.
- ➔ Vitamin D, phosphate binders and calcimimetics are used to treat patients with secondary hyperparathyroidism.
- ➔ High FGF23 levels are strongly associated with cardiovascular mortality and renal outcomes in CKD

4 OSTEONECROSIS

LEARNING OBJECTIVES

- ➔ Determine risk factors for osteonecrosis
- ➔ Describe and explain the X-ray and imaging features of the different stages of osteonecrosis
- ➔ Manage patients according to clinical and imaging staging

Osteonecrosis defines the death of bone and bone marrow due to impaired blood supply. This condition may occur in any bone, but mostly in subchondral weight-bearing bone such as in the femoral condyles and in the femoral head. If the damage is sufficiently important, it may lead to trabecular fractures or collapse of the articular cartilage (with subsequent osteoarthritis) and in severe cases, total collapse of the femoral head (figures 1 and 2), Osteonecrosis can involve any other epiphyseal extremity such as the humeral head, the tibial plateau and the talus. Involvement of the lunate and scaphoid bones of the hand is also possible.

4.1 Pathogenesis

The physiopathology mechanisms are incompletely understood. Osteonecrosis is caused by a compromised blood supply leading to ischaemia. The causes are obvious in traumatic osteonecrosis, for instance after a femoral neck fracture. However, in cases of atraumatic osteonecrosis, the aetiology has not been fully elucidated and could be related to intraluminal obliteration (vasculopathy) or extraluminal obliteration in the bone marrow. Risk factors associated with atraumatic osteonecrosis are shown in Table 1. Most risk factors are related to conditions, diseases and treatments which may have an impact on bone vascular flow. Glucocorticoid treatment is a major risk factor (Mankin, 1992), especially prolonged high doses of glucocorticoids (oral prednisone > 20 mg/d or high intravenous doses) where this complication typically occurs. 2–6 months after the onset of glucocorticoid therapy. Otherwise, patients with systemic lupus erythematosus or with positive anti-phospholipid antibody are also at risk (Houssiau et al, 1998).

Table 1. Risk factors for atraumatic osteonecrosis.

Biochemical factors
Anti-thrombin III deficiency
Protein C deficiency
Protein S deficiency
Resistance to activated protein C
Plasminogen activator deficiency
High plasminogen activator inhibitor
Secondary conditions of hyper coagulation
Intake of steroids
Alcoholism
Myelodysplastic syndromes
Pregnancy
Contraceptive use
Hyperlipidaemia
Collagen diseases
Ehlers–Danlos syndrome
Raynaud’s disease
Diabetes mellitus
Anti-phospholipidaemic antibodies (APLA)
Hematologic diseases
Haemophilia
Haemoglobinopathies
Polycythaemia
Metabolic diseases
Hyperparathyroidism
Cushing’s disease
Gaucher’s disease
Alimentary system diseases

Pancreatitis
Ulcerative colitis
Crohn's disease
Other risk factors
Smoking
Decompression disease
Radiation
Haemodialysis
HIV infection

4.2 Clinical symptoms

Patients often present with complaints of acute pain. For osteonecrosis of the femoral head, the pain is typically located in the groin and may radiate down the thigh to the knee. The pain is exacerbated by weight bearing. Movement of the hip joint may be normal or restricted. Shortening of the extremity may occur as a consequence of the collapse of the femoral head.

4.3 Imaging

Imaging is crucial for diagnosis and correlates with the natural history of the disease. The Steinberg classification is often used to stage osteonecrosis of the femoral head (Table 2) (Steinberg et al, 1995). The surface area and volume of the femoral head osteonecrosis can be assessed by CT scan or by MRI imaging.

Table 2. Steinberg classification (Steinberg ME, 1995)

Stage 0	Theoretical stage: Asymptomatic. All diagnostic tests are normal
Stage 1	X-Rays and CT-scan are normal. MRI and Tc99 are abnormal. Symptoms may or may not be present.
Stage 2	X-Rays are abnormal - With linear sclerosis or cysts. There is no Subchondral lucency Head of the femur is still spherical.
Stage 3	The femoral head starts to fail mechanically - with trabecular collapse. The radiolucent crescent sign is visible at the Subchondral endplate. The femoral head itself is still spherical.
	- Stage 3a. Crescent < 15%. Surgery still possible.
	- Stage 3b Crescent 15-30%
	- Stage 3c Crescent >30%
Stage 4	Flattening of the femoral head is now seen
	- Stage 4a <15% of the surface is collapsed depression <2mm
	- Stage 4b 15-30% collapse or 2-4mm depression
	- Stage 4c >30% collapse or >4mm depression
Stage 5	Any or all X-ray features may be present There is a decrease in joint space. Secondary Osteoarthritis is present with: Sclerosis / Cysts / Osteophytes
Stage 6	Extensive destruction

In early stages of the disease, conventional X-rays are normal (stage 0 and 1). MRI is more sensitive in these early stages and shows a circumscribed subchondral 'band-like' lesion with low signal intensity on T1-weighted images, corresponding to a sclerotic response of the bone surrounding the necrosis. This image sign is considered pathognomonic. MRI can also show bone marrow oedema and early subchondral necrotic lesions. If MRI is not available, bone scintigraphy with 99m-Technetium may be of help in the early stages. When the lesion progresses, this sclerotic zone becomes visible on X-ray (stage 2). A crescent lucent subchondral line resulting from a subchondral fracture characterises stage 3 (figures 3 and 4). The 'double-line' sign is seen on T2-weighted spin echo or turbo spin echo sequences and consists of a low signal intensity outer rim and a high signal intensity inner rim (figures 5 and 6). Flattening of the femoral head (stage 4) followed by joint space narrowing (stage 5) leads to extensive joint destruction (stage 6). Technetium-99m bone scanning is less sensitive than MRI, especially in early-stage lesions. Hence, it is not used for the diagnosis of or screening for osteonecrosis. In later stages, Technetium-99m bone scanning might show the so called "doughnut sign": increased uptake surrounding a cold area corresponding with increased bone turnover at the junction of dead and reactive bone (Figure 3). In case of multiple osteonecrosis, several sites may be visible on the scan.

Pain can be related to joint effusion, bone marrow oedema, subchondral bone fracture and collapse of the femoral head.

In case of hip pain with normal X-rays, other diagnoses are possible. Lumbar radiculopathy is easily differentiated by clinical examination. In hip algodystrophy, radiographs are often normal, and bone scans show non-specific increased tracer uptake. Bone oedema and joint effusion are visible on MRI, with no other signs of osteonecrosis. The diagnosis of stress fractures may be difficult, especially if located in the femoral head as well.

4.4 Treatment

Here we shall limit the discussion to osteonecrosis of the femoral head since this location is by far the most frequent and since this condition may be extremely disabling. Patients with limited osteonecrosis of the femoral head may have only modest symptoms. Many, however, develop osteoarthritis due to incongruity of the femoral joint surface. The treatment approach here is analogous to that for hip osteoarthritis; that is, medication against pain, physiotherapy and aids. If symptoms worsen with a severe reduction in the patient's daily living activities, hip joint replacement therapy is indicated. In contrast, hip arthroplasty early in the disease course is necessary with femoral head collapse and severe impairment. Several more or less validated treatment approaches are in use. These include surgical femoral neck-saving procedures, core decompression, vascularised or non-vascularised bone grafting, and rotational osteotomy.

Figure 1. Advanced osteonecrosis of the hip. X-ray of the left hip (anteroposterior and lateral view) showing advanced osteonecrosis with segmental flattening of the femoral head, fracture of the subchondral bone. Personal collection of Prof JD Laredo, Radiology, Lariboisière Hospital, Paris, France.

Figure 2. MRI showing osteonecrosis of the hip. The T1-weighted image shows a normal aspect of the right hip. However, on the left hip, segmental flattening of the femoral head, a band-like lesion with low signal and joint effusion can be seen. Personal collection of Prof JD Laredo, Radiology, Lariboisière Hospital, Paris, France.

Figure 2 (a to e). Bilateral osteonecrosis of the humeral head, in a 38 year old male patient known with juvenile type 1 diabetes, 4 years after combined kidney and pancreas transplantation. Six months later, osteonecrosis of the femoral heads.

Personal collection of Prof JP Devogelaer, Rheumatology, Cliniques Universitaires Saint - Luc, Brussels, Belgium.

Figure 2 a, b : Osteonecrosis of the right humeral head, MRI coronal view T1 (a), T2 weighted (b). Osteonecrosis of the upper portion of the humeral head with deformation of the head contour.

Figure 2 c, d, e: Osteonecrosis of the femoral heads without deformation of the head contour, MRI coronal view T2 (c), coronal view T1 (d), sagittal view T2 weighted image (e).

Figure 2 f, g, h: Osteonecrosis of the femoral heads. X-ray films, 4 years later in the same patient, showing irregularities of the epiphyseal contour.

Figure 2 i, j, k: Osteonecrosis of the humeral heads. X-ray films, again 4 years later in the same patient.

Figure 3. Bone scan in an 82 year old woman with late stage of avascular necrosis of the left hip.

SUMMARY POINTS

- The main cause of osteonecrosis is glucocorticoid treatment.
- MRI is the most sensitive imaging technique to diagnose osteonecrosis.
- More severe osteonecrosis can lead to osteoarthritis.

5 SCLEROSING BONE DYSPLASIAS**LEARNING OBJECTIVES**

- Classify the different forms of osteopetrosis and their related genes
- To recognize typical aspect of osteopoikilosis and melorheostosis on radiographs

Sclerosing bone dysplasias represent a large group of rare diseases with a hereditary component or not. These disorders are characterized by failure to resorb the primary spongiosa during embryogenesis, resulting in the accumulation of calcified cartilage matrix within the medullar cavity (like in osteopetrosis) or of focal densities into the medullary cavity such as in osteopoikilosis (Boulet et al, 2015). Osteopetrosis is the name given to a rare group of inherited diseases caused by failure of osteoclast function (Balemans et al, 2005). The presentation is highly variable, ranging from a lethal disorder that presents with bone marrow failure in infancy to a milder and sometimes asymptomatic form that presents in adulthood. Severe osteopetrosis is inherited in an autosomal recessive manner and presents with failure to thrive, delayed dentition, cranial nerve palsies (due to absent cranial foramina), blindness, anaemia and recurrent infections due to bone marrow failure. The adult-onset type (Albers-Schönberg disease) shows autosomal dominant inheritance and presents mainly with fractures, rarely with osteomyelitis, osteoarthritis (OA), vision impairment and sometimes as an incidental radiographic finding ('sandwich vertebrae') (figures 1 and 2). In many cases the genetic mutations responsible for osteopetrosis have been identified and affect the molecular machinery that the osteoclast uses to resorb bone matrix (table 1) (Michou and Brown, 2011). Thus, recessive osteopetrosis is caused mainly by mutations in *TCIRG1*, which encodes a component of the osteoclast proton pump, whereas mutations in the *CLCN7* gene, which encodes the osteoclast chloride pump, are responsible for a few cases of recessive and most cases of autosomal dominant osteopetrosis. Mutations in the carbonic anhydrase II gene are responsible for a syndrome of osteopetrosis and renal tubular acidosis due to failure of acid production within the osteoclast and renal tubules. Another recessive type of osteopetrosis, termed pycnodysostosis, is caused by mutations in cathepsin K, which is essential for degradation of bone matrix. Mutations in the *RANK* gene and *RANKL* gene cause osteoclast-poor osteopetrosis in which there is failure of osteoclast formation,

rather than function. Management of recessive osteopetrosis is difficult. Interferon γ treatment can improve blood counts and reduce the frequency of infections but in severe cases bone marrow transplantation is required to provide a source of normal osteoclasts that resorb bone normally. There is currently no treatment available for other rare sclerosing bone dysplasias, such as osteopoikilosis and melorheostosis (figures 3 and 4).

Figure 1. X-ray of the pelvis of a patient with Albers-Schönberg disease (Autosomal Dominant Osteopetrosis II). Note the “bone within a bone” appearance of the iliac wings, thick femoral cortices and osteosynthesis of a femoral neck fracture. Personal collection of Prof MC de Vernejoul.

Figure 2. X-ray of the lumbar spine of a patient with Albers-Schönberg disease (Autosomal Dominant Osteopetrosis II). Note the accentuation of the vertebral end-plate realizing a “rugger jersey” or “sandwich” appearance. Personal collection of Prof MC de Vernejoul.

Table 1. Classification of the main forms of human osteopetrosis

Type	Phenotype	Gene ^b
<i>Autosomal recessive osteopetrosis</i>		
1	Malignant neonatal or infantile form, bone sclerosis, fractures, pancytopenia, infections, hepatosplenomegaly, neurological abnormalities	TCIRG1
2	Intermediate form, low osteoclast numbers, short stature, fractures	RANKL
3	Intermediate form associated with renal tubular acidosis, short stature, mental retardation	CAII
4	Malignant infantile form, fractures, bone marrow involvement; or intermediate form	CLCN7
5	Malignant infantile form, fractures, bone marrow involvement	OSTM1
6	Variable severity, often intermediate	PLEKHM1
7	Severe form with low osteoclast numbers associated with hypogammaglobulinaemia	RANK
<i>Autosomal dominant osteopetrosis</i>		
1 ^a	Diffuse bone sclerosis predominating at the cranial vault, often asymptomatic, no fractures	LRP5
2	Sandwich vertebrae, bone-within-bone images, fractures, dental abscesses	CLCN7

a. This type is no longer classified as a form of osteopetrosis, because it is due to increased bone formation and not to decreased bone resorption.

TCIRG1 gene encoding the 1, ATPase, H⁺ transporting, lysosomal V0 subunit A3; RANKL or TNFSF11, tumour necrosis factor (ligand) superfamily, member 11; CAII, carbonic anhydrase II; CLCN7, chloride channel 7; OSTM1, osteopetrosis-associated transmembrane protein 1; PLEKHM1, pleckstrin homology domain containing, family M (with RUN domain) member 1; RANK or TNFRSF11A, tumour necrosis factor receptor superfamily, member 11a, NFκB activator; LRP5, low-density lipoprotein receptor-related protein

Figure 3. Incidental finding of an osteopoikilosis in a 22 years old man, characterized by multiple rounded blastic lesions. This disorder is inherited in an autosomal dominant mode of inheritance and cause by mutation in the LEMD3 gene.

Figure 4. Melorheostosis of the right tibia in a 26 years old man. This non-hereditary disorder is characterized by cortical and endomedullary hyperostosis in a candlewax appearance.

SUMMARY POINTS

- ➡ Most osteopetrosis is caused by mutations in genes important for osteoclast function.
- ➡ Recessive osteopetrosis occurring in children is severe and may require marrow transplantation.
- ➡ Other rare sclerosing bone diseases should be recognized on X-rays by rheumatologists

IN-DEPTH DISCUSSION I

Osteomyelitis

Osteomyelitis is an infectious disease of the bone and bone marrow. This common disease is often a challenge requiring input from rheumatologists, radiologists and orthopaedics. The main mechanisms for osteomyelitis are haematogenous spread to long bones metaphyses or vertebrae, contiguous spread due to local tissue infection, or infection associated with a periprosthetic joint. The disease is also commonly classified in acute, sub-acute and chronic osteomyelitis. Antibiotic therapy depends on the microorganism involved and treatment may require orthopaedic surgery. In the present section we shall limit the topic to atraumatic osteomyelitis and will not cover bone infection associated with traumatism.

Pathogenesis

In children, osteomyelitis preferentially affects the metaphyses of long bones, due to haematogenous spread, or contiguous spread from soft tissue infection. In adults, the most frequent site for haematogenous spread is the vertebrae. Osteomyelitis may also occur in long bones, by spread from a contiguous soft tissue infection or by reactivation of a former episode during childhood. Bone is relatively resistant to infections and infection requires large inocula from trauma or the presence of foreign bodies. Furthermore, *Staphylococcus aureus*, a common cause of osteomyelitis has the ability to survive intracellularly in osteoblasts, which protects him from humoral immunity and several classes of antibiotics. Finally, the spread of pus into vascular canals raises the intraosseus pressure and impairs blood flow. This may lead to ischemic necrosis and generation of sequestrae – devascularised bone fragments. The consequences of these conditions are the need for long-term antibiotic treatments and often surgical intervention.

Risk factors and type of microorganisms

As in a number of other infectious diseases patients with existing co-morbidities such as diabetes are at increased risk. In cases of bacterial spread from contiguous soft tissue, local factors have an influence (see Table 1). In this setting, attention should be drawn to rheumatology patients. Indeed, they already have chronic articular or bone diseases and have increased risk of infection due to immunosuppressive medicine including steroids and biologic agents. Sickle cell disease is another recognized risk factor.

The microorganisms causing osteomyelitis are shown in Table 2. They differ with age and depend on the underlying comorbidities. The most common etiologic agent is *Staphylococcus aureus*. Furthermore, attention should be drawn to the less common tuberculous osteomyelitis. In a Swedish study, *Mycobacterium tuberculosis* was identified in 27% of cases of vertebral osteomyelitis. Increased travelling and immigration have led to an increase in the incidence of tuberculosis in many European countries.

By haematogenous seeding, identification of the primary source is important.

This is obvious in the majority of cases (from skin, lung, urinary or postoperative wound infections). The possibility of a hidden abdominal infection, endocarditis or tuberculosis should be investigated if the source is not easily diagnosed.

Clinical symptoms

Symptoms, especially in vertebral osteomyelitis, may be vague and consist of low-grade fever, non-specific pain, tiredness, weight-loss and night sweats. This may lead to a considerable delay in diagnosis, in some cases to several months. In other cases, there is a severe back pain and eventually symptoms of nerve root compression or in late cases spinal cord compression. For long bone osteomyelitis patients in the acute phase may present with pain and impairment of motion in the affected extremity.

Osteomyelitis occurs with an increased frequency in patients with rheumatoid arthritis. In these cases, clinical signs and symptoms sometimes may mimic an exacerbation in the patient's inflammatory joint disease.

Biochemistry

Patients with osteomyelitis typically display an elevated white blood count with predominance of neutrophilic granulocytes as well as elevated ESR and CRP. Blood cultures will often be positive.

Imaging (Figures 1 to 3)

Plain x-rays are useful, but often insufficient in the initial disease stage. CT and MR scans are more sensitive. MR-scans have the advantage to identify and delineate surrounding soft tissue involvement. Bone scintigraphy with technetium 99m-labelled diphosphonate will show activity in the affected area. The investigation, however, is not able to distinguish infection from other disease causes.

Scintigraphy with labelled white cells or positron emission tomography (PET) scanning is also alternative modalities that can be used to make the diagnosis.

Diagnosis

A clinical diagnosis is made from anamnesis and clinical findings. The diagnosis is supported by laboratory tests, imaging preferably CT or MR scan and blood culture. In blood culture negative patients, invasive procedures with biopsy or aspiration of pus from the suspected area is necessary. It is suggested to repeat blood culture immediately after the biopsy. The search of a primary source is of particular importance.

Positive blood cultures without an obvious source should encourage the search for an endocarditis.

Treatment

Antibiotic treatment is started as soon as material for microbiologic investigation is secured. A frequent suspicion is infection with *Staphylococcus aureus* requiring treatment with oxacillin (cloxacillin) and gentamycin. Choice of antibiotics is subsequently adjusted to the established microbiology. In case of resistance to oxacillin, glycopeptides (vancomycin) should be proposed.

The properties of bone as mentioned earlier yields poor drug penetration and long term treatments with high doses are necessary. A typical regimen is 3 weeks of intravenous treatment followed by at least 5 weeks of oral therapy. In chronic osteomyelitis a much longer duration of treatment is necessary. In vertebral osteomyelitis stabilisation of the spine with a corset or body brace may be needed. Besides medical treatment consultation with orthopaedic surgeon is necessary in many cases. Abscess drainage, debridement surgery and surgical stabilisation are often needed. Response to treatment is followed by clinical parameters and inflammatory markers. Radiologic healing is typically not seen before weeks to months after cessation of antibiotics.

IN-DEPTH DISCUSSION II

Osteogenesis imperfecta in adult patients

Osteogenesis imperfecta (OI) is a genetic disorder of increased bone fragility and decreased bone mass. The clinical range of this condition is extremely broad, from cases that are lethal in the perinatal period to cases that present as primary osteoporosis. Classical OI is an autosomal dominant condition caused by a defect in type I collagen, the major component of bone extracellular matrix. Recent exciting developments have identified the genetic causes of severe recessive OI. These are rare conditions where the clinical presentation is extremely severe and will not often come to the rheumatologist's attention. However, it is possible that patients with monoallelic mutations that cause recessive OI will present clinically like primary osteoporosis.

Diagnosis of osteogenesis imperfecta in an adult patient

The diagnosis is straightforward in patients with familial history of fractures in whom typical extra-skeletal features are present. They include blue sclera and dentinogenesis imperfecta which are more usual in primary than in permanent teeth. Hearing loss starts in the 20s and progresses with age: half of patients older than 50 report hearing loss. Increased ligamentous laxity is frequent.

The skeletal phenotype is variable according to the type of OI and its mutation. All of them are listed in table I. In the mildest form of the disease (Type I of Sillence classification) fractures occur after ambulation. Fractures can also begin later in early mid-life where it presents as early onset osteoporosis. Fracture incidence then decreases markedly after puberty but can resume during pregnancy or lactation and with ageing (menopause in women). Vertebral fractures are common. Usually the height is normal and there is no scoliosis.

In Type III the number of fractures can be dramatically high during the patient's lifetime. The long bones are soft and deform/fracture easily due to normal muscle tension. Patients have extreme height deficiency and they develop scoliosis. They require intensive rehabilitation and often require a wheelchair for mobility.

In type V the phenotype is moderate to severe. The patients present with three typical findings: radiodense metaphyseal bands at the growth plate of long bones, hypertrophic callus and calcification of the forearm interosseous membrane.

The diagnosis can be difficult in the absence of familial history and in the absence of extra-skeletal signs. There is no minimum agreed common criterion to establish a clinical diagnosis.

Classification and genetic defect

Table I shows the different forms that have been described to date. Sillence proposed four types based on clinical and radiological criteria. Although this classification is still useful new types based on clinical and radiological or histological findings and on gene defects are now described.

All these new types are recessive, severe to lethal, and rarely come to the rheumatologist's attention. However, interestingly, it was shown that biallelic mutations of WNT10 are responsible for the extremely severe skeletal phenotypes, but patients with monoallelic mutations present like primary osteoporosis. Osteogenesis imperfecta should therefore be ruled-out in young subjects where a diagnosis of osteoporosis is made.

Table 1. Mutations and phenotype associated with the different types of OI

OI Type	Phenotype	Inheritance	Gene defect
I	mild	AD	COL1A1
II	lethal	AD or AR	COL1A1/COL1A2
III	progressive deforming	AD	COL1A1/COL1A2
IV	moderate	AD	COL1A1/COL1A2
V	moderate (hypertrophic callus)	AD	IFITM5
VI	Mineralization defect	AR	SERPINF1
<u>Defects in 3-hydroxylation of collagen I</u>			
VII	severe	AR	CRTAP
VIII	severe	AR	LEPRE1
IX	severe	AR	PPIB
<u>chaperone defect</u>			
X	severe	AR	SERPINH1
XI	severe	AR	FKBP10
C pro peptide cleavage defect			
XII	moderate	AR	SP7
XIII	mild to moderate	AR	BMP1
XIV	moderate to severe	AR	TMEM38B
XV	moderate to severe	AR	WNT1
XVI	lethal	AR	Homozygous deletion on chromosome 11?
XVII	mild to moderate	AR	SPARC
Legend AD: autosomal dominant, AR: autosomal recessive

X-ray and laboratory findings

X-rays show generalized osteopenia with thin cortices. Vertebrae often have central compression. Vertebral collapses may be difficult to assess in patients with scoliosis. The skull of a patient with OI often has wormian bones. In patients that have not received pamidronate, the dense metaphyseal bands are typical of OI type V.

Bone densitometry is useful in the mildest form and facilitates the follow-up. There is a general correlation between the Z-score and the severity of OI but discrepancy is not uncommon. Mineral metabolism is generally normal. 25 hydroxy-vitamin D should always be measured in order to treat possible insufficiency.

Figure 1 a : Vertebral compression fractures in a patient with OI type 1 (personal collection Pr de vernejoul)

Figure 1 b : dense metaphyseal bands in a patient with OI type V (personal collection Pr laredo)

Management

The management of OI is multidisciplinary and includes pain management, rehabilitation, and orthopaedic surgery in the most severe forms. Regular monitoring of hearing is important in adults.

In children bisphosphonate increases bone density, decreases pain and reduces fractures. In adults the benefit of bisphosphonate is less well proven but improvement in bone density has been shown with oral bisphosphonate. It is however difficult to prove that the treatment induces a reduction in fracture incidence due to the small number of patients involved in trials. Bisphosphonate should be prescribed only in patients with recent fractures. The period of treatment should not be too long as atypical fracture of the femur has been reported in adult OI patients on long term bisphosphonate treatment.

Anabolic treatment could be more appropriate and beneficial. Antisclerostin antibodies have been used successfully in murine models of OI. Recently, treatment with teriparatide has been tested in OI adult patients and was able to increase bone density and markers of bone formation in patients with less severe forms (type I). Larger trials are required to assess the benefits in the other forms of OI.

A previous version was coauthored by Véronique Hentgen, Anna Simon, Karin Mulders-Manders, Caroline Galeotti, Roberta Caorsi, Marco Gattorno, Katia Stankovic, Maria Antonietta Pelagatti, Gilles Grateau

LEARNING OBJECTIVES

This chapter gives an overview of:

- ➔ the pathogenesis of autoinflammatory diseases.
- ➔ the genetic and molecular defects that cause the most well-known autoinflammatory diseases.
- ➔ clinical features of autoinflammatory diseases and the typical clinical features of the best described autoinflammatory diseases.
- ➔ the diagnostic workup for suspected autoinflammation.
- ➔ treatment of autoinflammatory diseases.
- ➔ complications of autoinflammatory diseases.
- ➔ Follow up of autoinflammatory diseases.

1. Introduction

Autoinflammatory diseases are characterized by fever or other signs and symptoms of inflammation, such as elevation of acute phase proteins, without an infectious or autoimmune cause. Rather, unregulated activation of the innate immune system is mainly to blame.(Kastner et al, 2010)* In contrast to autoimmune diseases there are no high-titer autoantibodies or autoantigen-specific T cells, because the acquired immune system is not affected.

Many diseases, including more common diseases such as atherosclerosis, Crohn's disease or gout are at least partly explained by autoinflammation. One might see it as a immunological disease continuum with on one side the monogenetic autoinflammatory diseases, on the other side the monogenetic autoimmune diseases, and in the middle the mixed patterns and polygenetic diseases like Crohn's disease.(McGonagle 2009)

Systemic Juvenile Idiopathic Arthritis (SJIA) and its adult counterpart Adult Onset Still's Disease (AOSD) are examples of acquired autoinflammatory diseases. The genetic autoinflammatory diseases are rare.(Masters et al, 2009)* These are monogenic diseases with a distinct phenotype characterized by recurrent fever, accompanied by other inflammatory symptoms, such as skin rash, mucosal ulceration, arthritis, and serositis. Examples of these diseases are familial Mediterranean fever (FMF), cryopyrin associated periodic syndrome (CAPS), tumour necrosis factor (TNF)-receptor associated periodic syndrome (TRAPS), and mevalonate kinase deficiency (MKD, formerly known as the hyperimmunoglobulin D and periodic fever syndrome, HIDS). These classical autoinflammatory diseases usually have childhood onset and are inherited either in an autosomal dominant (TRAPS, CAPS) or recessive (FMF, MKD) fashion. Besides these well described diseases, many other autoinflammatory diseases have been identified since the introduction of the term autoinflammation almost 20 years ago. Some of these diseases have a known genetic defect, while in others no cause has been found so far. As the spectrum of autoinflammatory diseases keeps expanding, it is impossible to give a complete account of all these ultra-rare diseases here. Therefore, this chapter will give an overview of the pathogenesis, clinical picture, and treatment of the most common or best-described autoinflammatory diseases. We will also describe Schnitzler syndrome and adult onset Still's disease; two diseases with an interesting clinical picture for which patients may consult a rheumatologist. At the end of this chapter we summarize few other interesting autoinflammatory syndromes.

2. Pathogenesis

The common final pathway in many of the autoinflammatory diseases is overproduction of the pro-inflammatory cytokine interleukin-1 beta (IL-1 β). This cytokine is produced by large cytoplasmic protein complexes, called inflammasomes. Multiple inflammasomes have been identified, the best known of which is the NLRP3-inflammasome, named after the nucleotide binding and leucine-rich repeat containing protein 3 (NLRP3) at its core. (Figure 1) The NLRP3-inflammasome consists of three different proteins:

1. NLRP3. This protein consists of a leucine-rich repeat (LRR)-domain, a nucleotide binding and oligomerization (NACHT) domain and a pyrin (PYD) domain.(Hoffman et al, 2001) The LRR-domain is able to detect a variety of danger signals derived from damaged cells or micro-organisms. This in turn results in a conformational change that activates the NACHT domain and allows (figure 1A and B), NLRP3 to bind
2. The adaptor protein apoptosis-associated speck-like protein (ASC)(Agostini et al, 2004), which in turn recruits
3. The effector protein pro-caspase 1, which becomes autocleaved to active caspase-1.(Cerretti et al, 1992, Thornberry et al, 1992, Kuida et al, 1995) After this, caspase-1 is able to cleave the inactive procytokine pro-IL-1 β to its mature and active form IL-1 β .(Figure 1C). Likewise, caspase-1 can activate pro-IL-18 to mature IL-18.

Cryopyrin-associated periodic syndrome (CAPS) is the best-studied example of what happens when the NLRP3-inflammasome dysfunctions. CAPS is caused by gain-of-function mutations in the *NLRP3*-gene (Hoffman et al, 2001, Aksentijevich et al, 2002, Feldmann et al, 2002). The NLRP3 protein had also been referred to as cryopyrin in the past, hence the name Cryopyrin-associated periodic syndrome. The majority of CAPS-associated mutations are located in exon 3 of this gene, which encodes its NACHT-domain.

Although the cryopyrin-associated periodic syndrome is an autosomal dominant disorder, many patients don't have the pathogenic mutation in all of their cells. A low percentage (<5%) of mutant cells may be sufficient to give rise to the full inflammatory phenotype (Tanaka et al 2011). This phenomenon, known as somatic mosaicism shows how powerful the pro-inflammatory effect of these mutations can be.

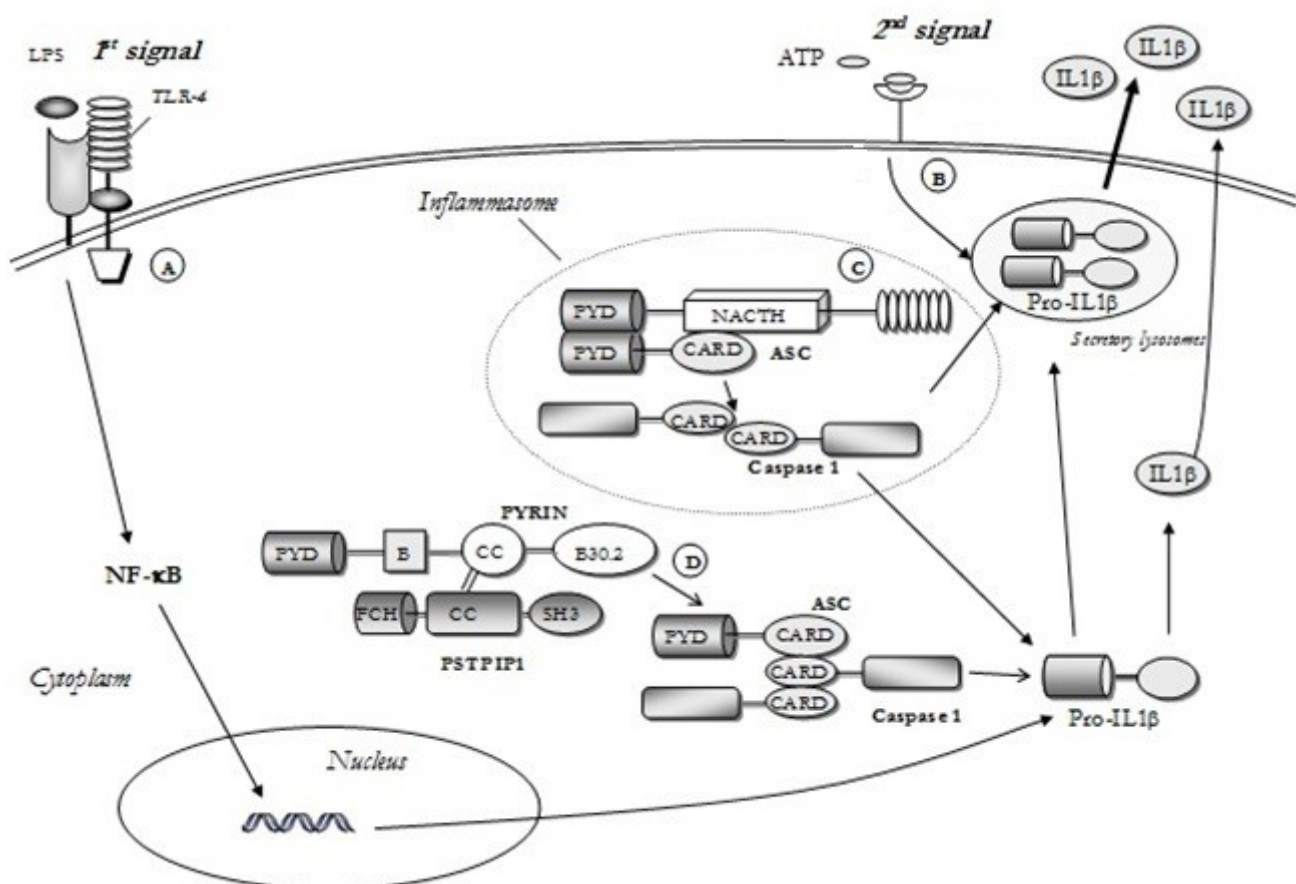

Familial Mediterranean fever (FMF) is caused by mutations in the Mediterranean fever (*MEFV*) gene, which encodes a protein, commonly called pyrin. This name is derived from the Latin word for fever. Pyrin is structurally related to NLRP3 and likewise can form inflammasomes. The natural signal to activate pyrin is reduced activity of RhoA protein in phagocytes (Xu et al, 2014). Some pathogens interfere with RhoA to impair host defence, but pyrin senses this alteration and therefore indirectly responds to the bacterial presence. Pyrin is then able to form its own inflammasome by combining with ASC and caspase-1 without involvement of NLRP3.(Manukyan et al, 2016). The FMF-associated *MEFV* alleles contain highly conserved founder mutations originating from around the Mediterranean basin. There are strong indications that heterozygote carriers of these mutations have had an evolutionary advantage during the great plague, because they allow for a strong inflammatory response to *Yersinia pestis*.(Chung et al. 2016) Besides FMF, pyrin may also be involved in several other autoinflammatory syndromes. Mutations at specific serine residues that abolish pyrin's ability to be inhibited by RhoA that give rise to a severe autosomal dominant autoinflammatory syndrome: pyrin-associated autoinflammation with neutrophilic dermatosis, PAAND (Masters et al 2016), while other mutations give rise to a distinct autosomal dominant hereditary autoinflammatory syndrome. (Stoffels et al, 2014). The

inflammation in mevalonate kinase deficiency (see below) is largely mediated via activation of the pyrin-inflammasome (Park 2016).

Pyrin is able to bind proline-serine-threonine phosphatase interacting protein 1 (PSTPIP1) (Shoham et al, 2003), a protein that is mutated in the autoinflammatory disease pyoderma gangrenosum, pyogenic arthritis and acne (PAPA) syndrome.

Figure 1. The NLRP3-inflammasome and the production of IL-1 beta.

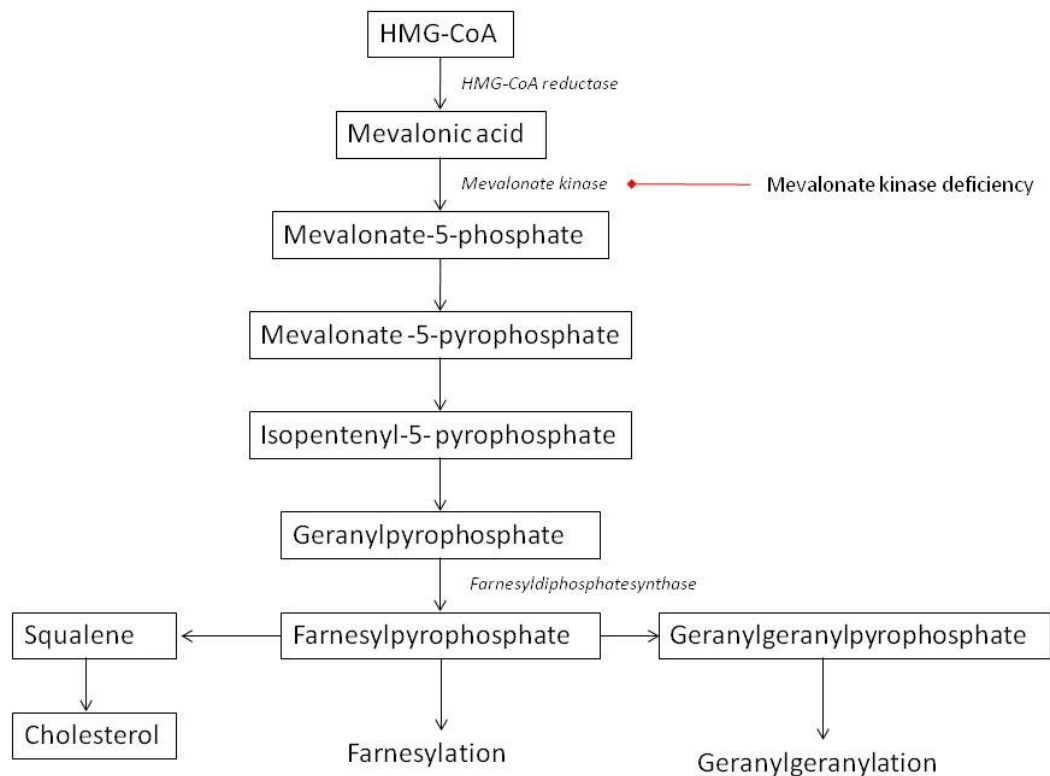

A: a first signal (in this case lipopolysaccharide (LPS) triggers the Toll-like receptor 4 (TLR-4), inducing the production of nuclear factor kappa-B (NF- κ B), which in turn induces the transcription of pro-interleukin-1 beta (pro-IL-1 β). B: a second signal (adenosine tri-phosphate (ATP) triggers the conversion of pro-IL-1 β to active IL-1 β . IL-1 β is then secreted. C: the nucleotide binding and leucine-rich repeat containing protein 3 (NLRP3)-inflammasome, containing the proteins NLRP3 (upper part, including a pyrin- (PYD) domain and a nucleotide binding and oligomerization (NACHT) domain); apoptosis-associated speck-like protein (ASC) (middle part), including a PYD and a caspase activation and recruitment domain (CARD); and two caspase-1 molecules, that also contain a CARD domain. D: interaction between pyrin and ASC. Shown is pyrin (upper part) and its PYD, B, CC and B30.2 domains and its association with proline-serine-threonine phosphatase interacting protein 1 (PSTPIP1).

In mevalonate kinase deficiency (MKD) the genetic defect lies in the mevalonate kinase gene (*MVK*). (Houten et al 1999; Drenth et al, 1999) Mutations in this gene lead to decreased production of the protein mevalonate

kinase. End-products of the mevalonate kinase pathway are cholesterol and non-sterol isoprenoids. (Figure 2) Decreased production of the latter forms the link between this pathway and the secretion of IL-1 β . Non-sterol isoprenoids are involved in protein prenylation, a process in which small non-sterol isoprenoids are coupled to larger proteins, influencing their activity or cellular localization. Deficiency of the non-sterol isoprenoid geranylgeranyl pyrophosphate (GGPP) leads to increased production of IL-1 β in patients with MKD (Mandey et al, 2006, Kuijk et al, 2008, Liao et al, 2013) via defective prenylation of the protein Ras homolog gene family, member A (RhoA). RhoA is an important inhibitor of the *MEFV*-gene product, pyrin. Hence impaired prenylation of RhoA in mevalonate kinase deficiency can lead to over-activation of pyrin and the excess production IL-1 β . (Park et al 2016)

Figure 2. The mevalonate kinase pathway

TRAPS is caused by mutations in the tumour necrosis factor (TNF) receptor superfamily 1A (*TNFRSF1A*)-gene, encoding the TNF-receptor type 1. (McDermott et al, 1999) At first, it was thought that these autosomal dominant mutations would lead to defective receptor shedding from the cell membrane, resulting in a decreased extracellular pool of soluble TNF-receptors to mitigate the inflammatory response. (McDermott et al, 1999, Huggins et al, 2004, D'Oswaldo et al, 2006, Lobito et al, 2006) However, defective shedding is not present in all TRAPS patient (Aksentijevich et al, 2001, D'Oswaldo et al, 2006, Lobito et al, 2006, Churchman et al, 2008) and TRAPS-associated mutations were found to influence protein folding, resulting in altered receptor trafficking and secretion. Mutated TNF-receptors accumulate intracellularly. (Todd et al, 2004, Lobito

et al, 2006, Todd et al, 2007)(figure 3) Ligand-independent signalling of these mutated receptors (Todd et al, 2004), induction of a stress response in the endoplasmatic reticulum with consequent production of reactive oxygen species (Bulua et al, 2011), or defects in TNF-mediated apoptosis (D'Ousualdo et al, 2006, Lobito et al, 2006) may lead to the inflammatory phenotype in TRAPS. Of all mutations found in TNFRSF1A, the R92Q- and P46L-variants (these are traditional names; official designations in the current nomenclature are R121Q and P75L) are somewhat unusual. These mutations do not lead to receptor misfolding and are present in low frequency in the healthy population. Nevertheless, they have also been associated with mild inflammatory phenotypes. As a consequence, the finding of one of these two mutations does not per se confirm a diagnosis of TRAPS.

Figure 3. Pathophysiologic mechanism of tumour-necrosis factor associated periodic syndrome. A shows the shedding hypothesis: decreased shedding would lead to a decreased pool of circulating soluble TNF-receptors that normally mitigate the immune response. B shows the trapping hypothesis, in which mutated receptors are accumulated in the endoplasmatic reticulum. Ligand-independent signalling leads to inflammation.

The pathogenesis of both Schnitzler syndrome and adult onset Still's disease (AOSSD) remains unknown. The beneficial effects of anti-IL-1 therapy indicate an important role for this cytokine in their pathogenesis.(de Koning et al, 2007, de Koning et al, 2011, Kadavath et al, 2015) For both diseases, no underlying genetic defect has been found. In a few patients with Schnitzler syndrome, somatic mosaicism of NLRP3 in myeloid cells has been found recently.(de Koning et al, 2015)* Somatic mosaicism may explain the late onset of Schnitzler syndrome. Other genetic defects have been described in limited numbers of patients, but their role remains unclear.

3. Clinical picture

The clinical picture of autoinflammatory diseases is highly variable between diseases, within the same disease, and even between episodes in the same patient. Autoinflammatory diseases are characterized by systemic inflammation. Common symptoms are:

- Fever, which may be accompanied by rigors or chills. Malaise, and anorexia
- Abdominal pain due to peritonitis, colitis or hepatosplenomegaly. It can be accompanied by diarrhoea, constipation, nausea or vomiting.
- Chest pain caused by pleuritis, pericarditis or of musculoskeletal origin.
- Lymphadenopathy: enlarged cervical, axillar, inguinal or abdominal lymph nodes may be present and can be painful.
- Arthralgia or arthritis, sometimes with persisting joint destruction.
- Myalgia affecting limbs and/or trunk.
- Neurological abnormalities, such as headache, aseptic meningitis, papilledema, ataxia, loss of vision, or hearing loss.
- Skin rash.
- Mucosal aphthous ulcers
- Ocular symptoms, such as conjunctivitis, iritis or uveitis.

Although inflammatory attacks may vary in the course of time, many patients will be able to recognize and describe signs and symptoms that define their own typical inflammatory attack. Patients may notice triggers for their attacks, such as emotional or physical stress, infections, cold exposure, vaccination or menstruation. Attack frequency may vary between and within patients. Auto-inflammation can lead to continuous inflammation, but inflammation-free intervals of several years are also possible. The same is true for the duration of inflammatory attacks, which can vary from continuous inflammation to episodes lasting only for a couple of hours to days.

The typical presentation of the classical monogenic autoinflammatory diseases, Schnitzler syndrome and adult onset Still's disease is described below. It is good to keep in mind that with improvement of techniques used for detection of genetic mutations, atypical presentations of the classical autoinflammatory diseases are increasingly seen.

Figure 4. Typical facial dysmorphism and skin rash in CAPS. A shows the typical frontal bossing, saddle back nose and mid-facial hypoplasia in a 3-year old child carrying a N477K-mutation in NLRP3. B: typical skin rash. Picture published with parental consent and reproduced with permission from Gattorno et al. J Clin Immunol. 2008; 28(suppl 1):S73-83. © J Clin Immunol

Familial Mediterranean fever

FMF is the most common autoinflammatory disease, especially in some populations. Prevalence is the highest in patients originating from around the Mediterranean basin, such as Arabs, Armenians, Turks and non-Ashkenazi Jews. Its inheritance is complex. Like in most autosomal dominant disease, gain-of-function mutations give rise to the disease. However, in FMF, a single mutant allele is usually insufficient to cause disease, whereas the presence of two affected alleles is likely to cause disease. Therefore FMF is mainly, but not exclusively, inherited in an autosomal recessive fashion. Most patients with FMF develop symptoms in infancy, but adult onset FMF has been described. A typical FMF attack starts with a prodromal phase with chills and malaise, followed by spiking fever that lasts 1-3 days. Attacks may be triggered by physical or emotional stress, infections or, in women, the menstrual cycle. Fever is accompanied by serositis: peritonitis, pleuritis, pericarditis or arthritis may be present. Due to sterile peritonitis, it is not uncommon for FMF patients to have had a healthy appendix removed because of suspected appendicitis. In boys, sterile periorchitis may mimic testicular torsion. Arthritis mainly affects large joints, such as knees, hips and ankles. Arthritic attacks can be protracted and joint symptoms may persist for days to weeks after fever has disappeared. Skin rash can be present. An erysipelas-like erythema located on the lower extremity is a rare but pathognomonic symptom of FMF. Protracted febrile myalgia syndrome is a very rare but severe manifestation of FMF. It is characterized by severe debilitating pain in the large muscle groups that may last for several weeks. IL-1 inhibition seems to be effective. (Mercan et al 2016)

Before the introduction of colchicine, proteinuria and renal failure due to secondary amyloid A (AA) amyloidosis developed in 75% of FMF patients. Since the introduction of effective therapy, the incidence of amyloidosis has decreased. In the past a 'type 2' FMF has been described in patients presenting with AA-amyloidosis associated with *MEFV* mutations in the absence of inflammatory attacks. It is now more commonly thought that these patients probably did have inflammatory attacks prior to the occurrence of amyloidosis, but that they were atypical and thus not recognized by patient and/or doctor.

Cryopyrin-associated periodic syndrome

Before the discovery of mutations in *NLRP3*, three different phenotypes that now fall in the CAPS spectrum were distinguished: familial cold autoinflammatory syndrome (FCAS), Muckle Wells syndrome (MWS) and neonatal onset multisystem inflammatory disease (NOMID, which is also known as chronic infantile neurologic, cutaneous and articular syndrome (CINCA)). Over the years, the CAPS-spectrum has extended and phenotypes with overlapping features are seen more and more. CAPS usually has its onset in infancy or early childhood. Mild CAPS phenotypes are characterized by short fever attacks that usually last up to 24 hours and can be induced by exposure to cold. A non-pruritic urticariform skin rash, arthralgia and conjunctivitis are common. Moderately severe phenotypes are associated with longer fever episodes, lasting up to several days. Progressive sensorineural hearing loss may be present. On the most severe end of the CAPS spectrum are the NOMID/CINCA phenotypes. Inflammatory symptoms, such as fever or skin rash may be present from birth or early infancy. Patients may have typical dysmorphias with frontal bossing, saddle nose and mid-face hypoplasia.(Figure 4) Bony overgrowth that predominantly affects the knees, hands and feet can be present.(Figures 5 and 6) Neurological symptoms, such as headache, papilledema, vision loss, hydrocephalus or aseptic meningitis are common in severe phenotypes.(Figure 7) Mental retardation and seizures have been described. Before adequate treatment was available, secondary amyloidosis was seen in approximately 25% of patient with moderate-to-severe CAPS.

CAPS is an autosomal dominant disease and a positive family history with fitting complaints in a first-degree relative can be helpful in the diagnosis, but mutations can also appear *de novo* and in about a third of patients disease is caused by somatic mosaicism.

Mevalonate kinase deficiency

Diseases associated with *MVK*-mutations form a phenotypic spectrum. Before the genetic cause was known, the hyperimmunoglobulin D and periodic fever syndrome (HIDS) and mevalonic aciduria (MA) were considered to be separate diseases. HIDS is now regarded as the least severe end of the MKD spectrum and is characterized by fever attacks that last up to a week with onset in early infancy. A typical feature of HIDS is that the first fever attack may be triggered by childhood vaccination. Symptoms that accompany fever are abdominal pain, vomiting, diarrhoea, lymphadenopathy, skin rash, oral aphthous ulcers, arthralgia or arthritis. Typically, serum immunoglobulin D (IgD) is elevated in these patients. On the most severe end of the MKD spectrum lies MA, a disease present from birth or early infancy, characterized by failure to thrive, psychomotor retardation, ataxia, cataract and facial dysmorphism. Fever may be present. Before the introduction of adequate therapy, many patients with MA died in early childhood. Phenotypes with overlapping features are increasingly seen and *MVK* mutations overlap between severe and mild phenotypes. MKD is an autosomal recessive disease and a positive family history can be helpful. The risk of amyloidosis in MKD is around 6%, depending on the specific *MVK* mutations involved. (ter Haar 2016)

Besides these clear inflammatory phenotypes the spectrum of diseases associated with mutations in *MVK* has recently expanded. Mutations in *MVK*, that may overlap with mutations found in 'classical' MKD, have been

described in patients with retinitis pigmentosa, early onset ulcerative colitis, the skin diseases disseminated superficial actinic porokeratosis and porokeratosis of Mibelli, cyclic neutropenia and macrophage activation syndrome. (Mulders-Manders et al, 2015)

Tumour necrosis factor receptor associated periodic syndrome

An important feature distinguishing TRAPS from the autoinflammatory diseases described above is the length of the inflammatory attacks. In TRAPS, inflammatory episodes last for several days to weeks. Fever can be accompanied by abdominal pain, arthralgia, skin rash (a migratory rash that moves from the distal to the proximal parts of an extremity is very typical, figure 8) and myalgia. Periorbital oedema is another distinguishing but rare symptom of TRAPS. Chest pain due to pleuritis or myalgia is common. Ocular symptoms including conjunctivitis, periorbital pain, uveitis and iritis can be present. Disease onset is in childhood in most patients, but adult onset

TRAPS is autosomal dominantly inherited, so positive family history can be helpful. In the past, AA amyloidosis was an important long-term complication of TRAPS, affecting up to 25% of untreated patients

Schnitzler syndrome

Schnitzler syndrome is characterized by late onset inflammation, with a median age of onset of 51 years. It is characterized by a non-pruritic urticarial skin rash, which can be accompanied by fever, bone pain, arthralgia or arthritis. Symptoms are progressive. The presence of monoclonal IgM or IgG paraprotein is a distinctive

feature, but symptoms can precede the presence of the M-protein for several years. Schnitzler syndrome is a non-hereditary disease. 15% of patients with Schnitzler syndrome develop Waldenström's macroglobulinemia within 10 years after the diagnosis.

Adult onset Still's disease

AOSD is characterized by fever, accompanied by arthralgia or polyarthritis and pharyngitis. A salmon-coloured skin rash, predominantly affecting the trunk and extremities is characteristic. Other symptoms are lymphadenopathy, hepatosplenomegaly, elevated liver enzymes, pneumonitis, and pleuritis. Beside high inflammatory markers (CRP), thrombocytosis, and neutrophilia, elevated serum ferritin levels are common in AOSD. A severe complication is the macrophage activation syndrome, which is a life-threatening disease, presenting with strongly elevated ferritin levels, coagulopathy, the absence or disappearance of thrombocytosis, and elevated liver enzymes.

The natural course of AOSD is highly variable. Some patients experience a single inflammatory episode, while in others episodic relapse of inflammation is present, and in some patients AOSD is a chronic disease.

4. Diagnostic workup for suspected autoinflammation

Thorough history taking and physical examination are the cornerstones of diagnosing autoinflammatory diseases. Focus should lie on the fever pattern, associated symptoms, triggering factors and family history. Experienced physicians with high exposure to these diseases may be able to diagnose some of these by pattern recognition, but clinical overlap is common. Patients should be seen during an inflammatory attack to validate symptoms and inflammation. Inflammatory markers, such as C-reactive protein (CRP) or serum amyloid A (SAA) should be measured during an inflammatory attack. Outside an attack, CRP and/or SAA may also be elevated, indicating smouldering subclinical inflammation. When during a clinical inflammatory attack no inflammatory markers are present, autoinflammation can be ruled out as the cause for the complaints. Further laboratory investigation should be guided by signs and symptoms present and should be aimed to exclude other causes for the inflammation. Although IL-1 β is central to the pathogenesis of the classical autoinflammatory disorders, serum levels of IL-1 β do not reflect the level of inflammation and should therefore not be used to test for the presence of autoinflammation. Diagnosis relies on recognition of the clinical picture and, increasingly, on detection of underlying genetic abnormalities. Laboratory investigations that may be helpful to distinguish autoinflammatory diseases are serum IgD, M-protein and ferritin. IgD is typically elevated in MKD, but it is neither sensitive nor specific: some MKD-patients never have elevated IgD and IgD may also be elevated in other inflammatory conditions, including FMF. Elevated IgA can be present in MKD. Schnitzler syndrome is characterized by the presence of monoclonal M-protein, typically IgM, but IgG paraproteinemia can also be present. As ferritin is an acute phase reactant, it may be elevated in patients with any inflammatory disease, but very high levels in combination with a fitting clinical picture are typical for

AOSD. Measurement of urinary mevalonic acid during febrile attacks can support a diagnosis of HIDS with high sensitivity. (Jeyaratnam 2015). However, the technology to detect mevalonic acid is not widely available. Measurement of MVK-activity in patient cells is the gold standard to diagnose mevalonate kinase deficiency, but the method is only available in very few highly specialized research laboratories. Therefore diagnosis does not depend on enzymatic studies.

Table 1. Diagnostic criteria for familial Mediterranean fever (FMF). Sensitivity and specificity are >95% and >97%, respectively.

Tel-Hashomer criteria (Definite diagnosis: 2 major criteria OR 1 major and 2 minor criteria. Possible diagnosis: 1 major and 1 minor criterion)

Major criteria

Recurrent febrile episodes associated with peritonitis, pleuritis or synovitis
AA-amyloidosis without a predisposing disease
Favourable response to colchicine

Minor criteria

Recurrent febrile episodes
Erysipelas-like erythema
Positive history of FMF in a first-degree relative

Livneh criteria (1 major criterion OR 2 minor criteria)

Major criteria

Typical attacks* of:

- Peritonitis (generalized)
- Pleuritis (unilateral) or pericarditis
- Monoarthritis (knee, hip or ankle)
- Fever

Minor criteria

1-2 incomplete attacks\$ affecting one or more sites:

- Abdomen
- Chest
- Joint
- Exertional leg pain

Response to colchicine

* Typical attack: ≥ 3 episodes with rectal temperature $\geq 38^{\circ}\text{C}$ lasting 12-72 hours

\$ Incomplete attack: recurrent painful attacks that do not fulfil all criteria for typical attacks (lower body temperature OR shorter or longer duration OR abdominal pain without peritonitis OR localized abdominal attack OR arthritis in other joints than specified).

Table 2. Diagnostic criteria for Schnitzler syndrome¹**Major criteria (≥ 1 present)**

(Chronic) urticarial rash

Monoclonal IgM or IgG

Minor criteria (≥ 2 present)

Intermittent fever

Arthralgia or arthritis

Bone pain

Lymphadenopathy

Hepato- or splenomegaly

Elevated erythrocyte sedimentation rate

Leukocytosis

Bone abnormalities (radiological or histological)

¹ Only when other causes have been excludedAdapted from: de Koning et al. Diagnostic criteria for Schnitzler syndrome. *Semin Arthritis rheum.* 2007

5. Diagnosis

CAPS, FMF, MKD and TRAPS can be confirmed by genetic analysis with detection of mutations in their respective causative genes, but mutation-negative forms of these diseases have been described, just like FMF or MKD associated with heterozygous mutations, possibly because mutations are not picked up with the current diagnostic techniques. Diagnostic criteria with high specificity are available for FMF (Tel-Hashomer (Sohar et al, 1997) or Livneh criteria (Livneh et al, 1997), table 1), Schnitzler syndrome (de Koning et al, 2007) (table 2) and AOSD (Yamaguchi criteria (Yamaguchi et al, 1992), table 3) and recently new sets of diagnostic clinical criteria for FMF, MKD, TRAPS and CAPS have been proposed (table 4), which have a sensitivity and specificity of 80-96 and 89-92%, respectively. (Federici et al, 2015) In FMF, a positive reaction to treatment with colchicine may be an additional clue that FMF is present and can therefore be used as a diagnostic test. Further recommendations for the genetic confirmation of FMF can be found in the most recent SHARE guidelines. (Giancane et al, 2015) As described in the section on patho-physiology, detection of R92Q- (R121Q) or P46L- (P75L) mutations in TNFRSF1A does not confirm TRAPS, as these mutations are present in low frequency in the general population. Diagnostic multi-gene panels that enable simultaneous sequencing of dozens or even hundreds of autoinflammation-associated genes are increasingly available and may be helpful in the diagnostic workup, as these will be less time consuming than doing multiple consecutive monogenetic analyses and may lead to the identification of new autoinflammatory diseases.

Table 3. Yamaguchi criteria for the diagnosis of adult onset Still's disease (AOSD)¹ (≥5 present of which ≥2 major criteria)**Major criteria**

Fever >39°C for ≥1 week
 Arthralgia or arthritis for ≥2 weeks
 Typical salmon-coloured rash
 Leukocytosis >10x10⁹/L with >80% polymorphonuclear cells

Minor criteria

Sore throat
 Recent and significant lymphadenopathy
 Hepatomegaly or splenomegaly
 Elevated liver enzymes
 No antinuclear antibodies (ANA) and rheumatoid factor (IgM)

¹AOSD can only be diagnosed when other causes are excluded.

6. Treatment

Colchicine

The drug of first choice in FMF is colchicine (Ozen et al, 2016), as this drug is the only drug that has been proven to protect patients against the development of secondary AA amyloidosis. Its mechanism of action in FMF is unknown. On average, a dose of 1.0-1.5mg/day, which can be taken in a single daily dose or divided in multiple doses (Ozen et al, 2016), is effective. Side effects are predominantly of gastrointestinal origin, such as diarrhoea, nausea and abdominal pain. It is important not to stop colchicine when it is clinically ineffective or when side effects are present. In all patients the highest tolerated dose should be continued because of colchicine's protective effect against amyloidosis. In the few patients in whom colchicine is truly ineffective (in most patients ineffectivity will more likely be caused by incomplete compliance rather than true colchicine-resistance) addition of IL-1 inhibition can be very effective. Colchicine can be safely used during conception, pregnancy and lactation as is illustrated by multiple cohort studies.

Colchicine can also be used as a diagnostic test in patients with high suspicion of FMF. When colchicine is effective in a patient from a high-risk population and with a compatible clinical picture, FMF is the most likely diagnosis, even when no *MEFV*-mutations are found. During colchicine therapy, monitoring of liver enzymes and creatinin kinase (CK) should be checked regularly, especially in patients with decreased kidney function, as these patients are more susceptible for side effects and toxicity. (Giancane et al, 2015, Ozen et al, 2016)

Interleukin 1 targeting inhibition

The use of interleukin-1 targeting drugs in autoinflammatory diseases is described in detail in the in-depth discussion 2 that accompanies this chapter.

As outlined earlier in this chapter, overproduction of the pro-inflammatory cytokine IL-1 β is the most important feature in the pathophysiology of many autoinflammatory diseases. This is reflected by the positive effects of IL-1 inhibiting drugs in these diseases. The first IL-1 targeting drug to be widely available was anakinra, a recombinant IL-1 receptor antagonist. It has been shown to be effective in CAPS, FMF, MKD, TRAPS, Schnitzler syndrome and AOSD (Ter Haar et al, 2013, ter Haar et al, 2015, Ben Zvi 2016)* and has become standard of care, except for FMF, in which colchicine is the drug of first choice (see the section on this drug later in this chapter). The use of anakinra may lead to instant cessation of inflammation in autoinflammatory diseases. (Figure 9) and because of this it can also be used as a diagnostic test for IL-1 mediated inflammation. When signs of autoinflammation are present and other causes have been excluded, anakinra may be initiated. If it is effective, autoinflammation becomes a more likely diagnosis. An alternative for anakinra is canakinumab, a long-acting specific anti-IL-1 β monoclonal antibody. It has proved effective in Systemic JIA and CAPS. (Lachmann et al. 2009; Ruperto et al 2012) Based on the preliminary results of a large

double blind placebo controlled trial canakinumab has now also been registered for the treatment of, TRAPS, MKD and colchicine-resistant FMF.

The third IL-1 targeting drug available is rilonacept, a construct of two extracellular chains of the IL-1 receptor complex fused to the Fc-proportion of IgG. It has been approved for the treatment of CAPS and has been shown to be effective in colchicine resistant FMF.

The most common side effect of IL-1 inhibiting drugs is increased susceptibility for infections. Mild upper respiratory tract infections are the most common and severe infections are rare. With the use of anakinra, local injection site reactions are common. These can be extremely painful and this may hamper therapy.

Figure 9. Rapid effect of anakinra in a patient with CAPS. On day 0 before start of anakinra an urticarial rash is seen, which is completely absent one day after the first injection (day 1). Picture reproduced with permission from Gattorno et al. J Clin Immunol. 2008; 28(suppl 1):S73-83. © J Clin Immunol

Interleukin-6 inhibition

When anti-IL-1 therapy is ineffective in patients with an autoinflammatory disease, tocilizumab can be tried. Tocilizumab is a monoclonal antibody against the interleukin-6 (IL-6) receptor that has been registered for the treatment of rheumatoid arthritis and systemic onset juvenile idiopathic arthritis (SoJIA) and has shown to be effective in Schnitzler syndrome, AOSD, MKD and TRAPS. Side effects are increased susceptibility for infections, elevated liver enzymes and haematological abnormalities. IL-6 is an important cytokine in the production of CRP. Because of this, during tocilizumab treatment, CRP cannot be used to monitor disease activity.

Corticosteroids

Corticosteroids may be effective in autoinflammatory diseases such as AOSD, MKD, TRAPS and CAPS, but their effect is less than the effects of anti-IL-1 therapy (Ter Haar et al, 2013, ter Haar et al, 2015)* and side effects are common and may be severe. Because of this, corticosteroids are not preferred as maintenance treatment for patients with autoinflammatory diseases. However, in patients with infrequent episodes of TRAPS or MKD attacks may be managed with a short course of corticosteroids.

TNF-inhibition

There are no prospective trials comparing the effects of IL-1 inhibition and drugs that target TNF, such as etanercept or adalimumab. These may be effective in some patients with TRAPS (Ter Haar et al, 2013), but their effect may decline over time and because of this anti-IL1 treatment is preferred. (ter Haar et al, 2015) Anti-TNF may be used as a rescue drug in other anti-IL-1 resistant auto-inflammatory diseases. It has shown to be effective in over half of patients with MKD (ter Haar et al, 2015) and in AOSD or FMF anti-TNF may be effective, but its effect is generally less than the effect of colchicine (in FMF) and anakinra, and in AOSD it may even lead to exacerbations of the disease. (Kaneko et al, 2010)

7. Follow up

All patients with an (suspected) autoinflammatory syndrome should be followed up regularly for the evaluation of treatment and detection of drug side effects and complications. The most common complication of autoinflammatory diseases is secondary amyloidosis. This is described into more detail in in-depth discussion 1 accompanying this chapter. Periodical measurement of urinary protein should be performed in all patients with (suspected) autoinflammatory diseases to screen for secondary renal amyloidosis, although the risk of this is highest in FMF, TRAPS and moderate to severe CAPS and relatively low in MKD, Schnitzler syndrome and AOSD. CAPS can be complicated by vision loss and patients with moderate to severe CAPS are at high risk of developing sensorineural hearing loss. Because of this, periodical ophthalmologic and audiometric evaluation should be performed. MKD and AOSD can be complicated by the potentially fatal macrophage activation syndrome, also known as secondary haemophagocytosis. This syndrome is characterized by pancytopenia, liver failure, coagulopathy and neurological symptoms. Patients are generally very ill with fever and inflammation. ESR may be deceptively normal or even low because fibrinogen is consumed in the coagulopathy. Its cause is unknown. In patients with Schnitzler syndrome, M-protein should be measured regularly as 15% of these patients develop Waldenström's macroglobulinemia after 10 years.

8. Other rare auto-inflammatory syndromes like interferonopathies, granulomatous and pyogenic diseases.

8.1. Interferonopathies

Type 1 interferons (interferon alfa (IFN- α) and interferon beta (IFN- β) are important pro-inflammatory cytokines that play a role in host defence against intracellular pathogens. Their secretion is induced by stimulations of pattern recognition receptors, such as the Toll-like receptors (TLR). Type 1 interferons bind the interferon- α receptor (IFNAR) located on the cell surface and stimulation of IFNAR leads to activation of the Janus kinase (JAK)-signal transducer and activator of transcription (STAT) pathway, inducing transcription of interferon-stimulated gene (ISG) resulting in a consequent immune response.(Lee-Kirsch et al, 2015)

The term type 1 interferonopathies was first used in 2011 to describe a group of hereditary disorders associated with abnormal upregulation of type 1 interferons. Since the introduction of this term, the number of type 1 interferonopathies has been expanding rapidly. Most of them are very rare and therefore not all type 1 interferonopathies are described here. Examples of type 1 interferonopathies are:

- STING-associated vasculopathy (SAVI). This is an early onset disease with predominant vasculopathy, characterized by necrotic skin lesions on the face, fingers and toes, ears and nose, accompanied by fever episodes and interstitial lung disease or lung fibrosis.
- Proteasome associated autoinflammatory syndromes constitute an expanding group of disorders is caused by mutations affecting component proteins of the immunoproteasome. Clinically these are characterised by recurrent fever and various combinations of nodular skin rash, panniculitis, lipodystrophy, myositis and central nervous system involvement. An example is chronic atypical neutrophilic dermatosis with lipodystrophy and elevated temperature (CANDLE). It is an autosomal recessive disease characterized by early-onset recurrent fever, associated with skin lesions, swelling of eyelids and lips, failure to thrive, growth retardation, lipodystrophy, arthropathy and myositis. Visceral inflammation may be present. As it was first described in 1939 it is not newly identified, however, it was only recently classified as an autoinflammatory disease when it was found out that mutation in the gene encoding low molecular weight protein 7 (LMP7) cause CANDLE. LMP7 is a subunit of the immuno-proteasome; mutations lead to decreased proteasome activity and consequently increased production of proinflammatory cytokines. High dose steroids are very effective in CANDLE.
- Aicardi-Goutières syndrome. This rare disease is characterized by neonatal onset leukoencephalopathy, dystonia, seizures, fever, developmental delay and microcephaly. Other symptoms include liver enzyme elevation, arthritis, thrombocytopenia, lymphocytopenia, presence of antinuclear antibodies (ANAs) and cold-induced skin lesions. The pheno-type may differ largely between patients from one family. At least seven different genes that cause Aicardi-Goutières syndrome have been described.

- Retinal vasculopathy with cerebral leukodystrophy: this is an autosomal dominant disease characterized by cerebrovascular events, dementia and loss of vision. Disease onset is in early adulthood. Other symptoms may be headache, glomerulopathy and Raynaud's phenomena.
- Familial chilblain lupus (FCL). FCL is a very rare form of cutaneous lupus erythematosus with early childhood onset. Characteristic symptoms are red-blue skin lesions on the fingers, toes, nose, cheeks and ears. Other symptoms include the presence of ANAs, lymphopenia and arthralgia.

The optimal treatment for type-1 interferonopathies is unknown. Drugs targeting IFN- α or β , IFNAR or the JAK/STAT pathway may be effective and can be tried in these patients.

8.2 Granulomatous autoinflammatory syndromes

8.2.1 Blau syndrome

Blau syndrome, which is also known as familial juvenile systemic granulomatosis, is an autosomal dominant disease characterized by a triad of arthritis, dermatitis and uveitis due to non-caseating granulomatous inflammation. Disease onset is usually during the first years of life. Fifty percent of patients develop cataract and approximately one third eventually develops secondary glaucoma. Blau syndrome is caused by mutations in the gene encoding nucleotide binding oligomerization domain containing 2 (NOD2), a receptor able to recognize certain bacterial cell wall components and upon recognition upregulates NF- κ B, leading to an inflammatory response. It is also involved in autophagy and apoptosis. At least 17 mutations in NOD2 are associated with Blau syndrome and mutations in NOD2 are also found in early-onset sarcoidosis and Crohn's disease.

8.3. Pyogenic autoinflammatory syndromes

8.3.1 Pyogenic arthritis, pyoderma gangrenosum and acne (PAPA) syndrome

Pyogenic sterile arthritis (PAPA) syndrome is an autosomal dominant disease characterized by sterile arthritis, pyoderma gangrenosum and cystic acne. Disease onset is in childhood, with pyogenic oligoarthritis as presenting symptom. This sterile arthritis eventually leads to synovial and cartilage destruction. Skin lesions appear in the second decade of life. Acne, ulcerative skin lesions mimicking pyoderma gangrenosum, skin abscesses and hidradenitis are symptoms of PAPA syndrome.

Mutations in the gene encoding proline-serine-threonine phosphatase interacting protein 1 (PSTPIP1) cause PAPA syndrome. PSTPIP1 is able to bind pyrin, forming a complex regulation the inflammasome.

PAPA syndrome is usually responsive to oral glucocorticoid treatment. Steroid resistant patients may benefit from anti-TNF or anti-IL-1 therapy.

8.4 Other autoinflammatory syndromes

8.4.1. Periodic fever, aphthous stomatitis, pharyngitis and adenitis (PFAPA) syndrome.

Periodic fever, aphthous stomatitis, pharyngitis and adenitis (PFAPA) syndrome was first described in the late 1980s. (Marshall et al, 1987) It may be the most common autoinflammatory diseases, but it is difficult to estimate its incidence as it is underrecognized. PFAPA is a disease with a usual onset before the age of 5. Its clinical picture is characterized by frequent and recurrent episodes of fever, accompanied by pharyngitis, cervical adenitis and aphthous stomatitis. Other symptoms are headache, vomiting, abdominal pain, arthralgia and myalgia. Symptoms usually cease before or during adolescence; the cause for this is unknown. PFAPA has been described in adults, but it is uncertain whether these cases represent the same disease. Little is known on the pathogenesis of PFAPA and no genetic defect has been found so far.

The only evidence based therapy in PFAPA is (adeno-)tonsillectomy. However, follow up of these studies has been short. Most patients benefit from short courses of corticosteroids during attacks, but their use may increase attack frequency. (ter Haar et al, 2015) A small trial showed that colchicine may reduce attack frequency in PFAPA. (Butbul Aviel et al, 2016) Other treatments that have been reported in small numbers of patients are cimetidine, and anakinra.

8.4.2. NLRP12-associated periodic syndrome

The NLRP12-associated periodic syndrome (Jeru et al, 2008) presents with recurrent fever, accompanied by urticarial skin rash, myalgia, arthralgia, sensorineural hearing loss, aphthous ulcers, lymphadenopathy and/or abdominal pain. Attacks may be triggered by exposure to cold, physical exertion or fatigue and the phenotype can resemble CAPS.

The protein NLRP12 is part of the nucleotide binding and leucine-rich repeat containing protein family, just like NLRP3, the protein involved in the pathogenesis of CAPS. Just like NLRP3, NLRP12 is able to form an inflammasome by combining with ASC and procaspase-1 and is involved in the up-regulation of NF- κ B. Mutations may interfere with this, leading to upregulation of the proinflammatory pathway.

8.4.3. Deficiency of interleukin-1 receptor antagonist (DIRA)

Deficiency of interleukin-1 antagonist (DIRA) is a disease with neonatal onset. It is characterized by multifocal osteomyelitis, periostitis and pustules, which may be local or generalized. (Aksentijevich et al, 2009)

DIRA is caused by mutations in the gene encoding interleukin-1 receptor (*IL-1RN*), leading to deficiency of the IL-1 receptor antagonist, which normally functions as an inhibitor of circulating IL-1 α and β . Treatment with recombinant human IL-1RA (anakinra) is very effective in DIRA.

8.4.4. NLRC4 associated autoinflammatory syndromes

Gain of function mutations in the gene encoding the inflammasome protein NLRC4 give rise to a spectrum of autosomal dominant diseases. Mildly affected patients have recurrent urticariform rash with conjunctivitis myalgias and arthritis. The other extreme of the clinical spectrum is characterised by severe sterile enterocolitis and susceptibility to the potentially lethal macrophage activation syndrome. (Canna et al 2014) Interleukin-18 and its downstream mediator gamma-interferon (IFN γ) appear to central to its pathogenesis.

8.4.5. NLRP1-associated autoinflammation with arthritis and dyskeratosis is an ultra rare disorder due to mutations in the gene encoding NLRP1, which is another inflammasome protein. The clinical phenotype includes diffuse skindyskeratosis, autoinflammation, autoimmunity, and arthritis. (Grandemange et al 2016)

8.4.6. *Deficiency of the interleukin-36 receptor antagonist (DITRA)*

Deficiency of the interleukin-36 receptor antagonist (DITRA) is a rare autosomal recessive disease associated with episodic fever, skin rash and pustular psoriasis, (Marrakchi et al, 2011) Mutations in the gene encoding the IL-36 receptor antagonist cause DITRA and deficiency of the receptor for the pro-inflammatory cytokine interleukin-36 leads to this inflammatory phenotype. Corticosteroids, retinoids, cyclosporine, methotrexate, anti-TNF and anakinra may all be effective in DITRA. Recently, ustekinumab was shown to be effective in two therapy resistant patients. (Bonekamp et al 2017)

8.4.6. *Majeed's syndrome*

The first report on the autosomal recessive Majeed's syndrome described a clinical picture with chronic recurrent multifocal osteomyelitis, congenital anaemia and inflammatory dermatitis. Majeed's syndrome is caused by mutations in the gene encoding lipin-2 (LPIN2). The exact function of this protein is unknown, but besides its role in inflammation, it also plays a role in lipid metabolism. Oral steroids can be effective. IL-1 blockade has been shown to effectively control inflammation in some cases.

8.4.7 Haploinsufficiency of A20 and related disorders of ubiquitinylation

Another rare autosomal dominant autoinflammatory disease is caused by loss-of function mutations in *TNFAIP3*, encoding A20, a negative regulator of NF κ B and of the NLRP3 inflammasome. Patients have an early onset febrile disease that is somewhat similar to Behçet's disease, with ocular inflammation, oral and genital ulcers and polyarthritis, but may include organ specific autoimmunity as well. (Zhou et al 2016). It is one of an emerging group of autoinflammatory disorders in which protein ubiquitylation is disturbed.

8.4. Auto inflammation with immunodeficiency

DADA2

Loss-of function mutations in both alleles of *CECR1* encoding Adenosine Deaminase-2 (ADA2) are associated with a spectrum of vascular and inflammatory phenotypes, ranging from early-onset recurrent stroke to systemic vasculopathy or vasculitis combined with a mild immunodeficiency (hypogammaglobulinemia) and hepatosplenomegaly. Patients with ADA2 deficiency (DADA2) have significantly diminished ADA2 activity in plasma. Treatment is directed to prevention of recurrent infections with antibiotic prophylaxis and/or immunoglobulin substitution. (Zhou 2014, Navon-Elkan 2014) Inflammation might be treated with anti-TNF. Anticoagulants are given to prevent strokes.

SIFD

A syndrome of congenital sideroblastic anaemia (CSA) associated with B-cell immunodeficiency, periodic fevers, and developmental delay (SIFD), is caused by partial loss of function mutations in *TRNT1*, the gene encoding the CCA-adding enzyme essential for maturation of both nuclear and mitochondrial transfer RNAs. (Chakraborty 2014)

9. Conclusion

Autoinflammatory diseases are rare diseases characterized by chronic or episodic inflammation. Many various phenotypes have been described. CAPS, FMF, MKD and TRAPS are the most best-known. Other autoinflammatory diseases are increasingly reported, but most of them are rare. Diagnoses are based on a clinical picture with signs and symptoms of inflammation and sometimes with the help of detection of genetic abnormalities. Interleukin-1 targeting drugs are very effective in most classical autoinflammatory diseases. Exceptions are FMF, where colchicine is the drug of first choice, and the interferonopathies, where drugs targeting IFN or the JAK/STAT pathway are most effective. The main long-term complication of autoinflammatory diseases is AA amyloidosis.

IN-DEPTH DISCUSSION I

AA Amyloidosis in auto inflammatory diseases

One of the most serious complications of auto inflammation is the development of AA amyloidosis. Although the incidence of this potentially life-threatening disease has decreased since the introduction of targeted anti-inflammatory therapy, it is still an important long-term complication of these diseases.

Pathogenesis

Amyloidosis is caused by deposition of insoluble fibres in the extracellular matrix with disruption organ structure and organ function. In AA amyloidosis the amyloid fibrils consist of insoluble degradation products of the acute phase reactant serum amyloid A (SAA). The transcription of the hepatic protein SAA depends on several proinflammatory cytokines, amongst others IL-1 and IL-6. Therefore AA amyloidosis, which is also known as secondary amyloidosis, is associated with long-term systemic inflammation. The normal serum concentration of SAA is <10mg/L. During systemic inflammation this concentration can increase 1000-fold. There is a significant association between the duration of elevated SAA serum levels and the development of AA amyloidosis.

In AA amyloidosis, amyloid depositions primarily affect the kidneys. Other organs such as heart, liver, bone marrow and spleen may also be affected. Involvement of intestine, skin, thyroid, testes or adrenal glands is rare and only seen in patients with long-term untreated amyloidosis.

Epidemiology

The incidence of AA amyloidosis in auto inflammatory diseases has been studied before targeted treatment was available. The risk of developing amyloidosis varies between diseases, with the highest risk for patients with familial Mediterranean fever (FMF). In the pre-colchicine era over half of FMF patients developed amyloidosis. In untreated TNF-receptor associated periodic syndrome (TRAPS) amyloidosis was present in 10-20% of and in cryopyrin-associated periodic syndrome (CAPS) incidence was 25% with higher incidence in patients with the clinical phenotype Muckle-Wells syndrome than in familial cold auto inflammatory syndrome. AA amyloidosis is rare in mevalonate kinase deficiency (MKD): approximately 10 patients with hyperimmunoglobulinaemia D and periodic fever syndrome (HIDS) have been published worldwide (Obici 2012). AA amyloidosis is also rare in Schnitzler syndrome. (De Koning Semin Arthr Rheum 2007) It is unclear why some patients with the same level of inflammation never develop AA amyloidosis, while others do. There may be an association with polymorphisms in the SAA-gene or certain genotypes.

There can be a prolonged period of time between onset of inflammation and presentation of AA amyloidosis, but in some patients amyloidosis develops rapidly. In a cohort of 46 patients with an auto inflammatory disease (FMF, CAPS, TRAPS or MKD) and amyloidosis, median time between onset of symptoms of auto inflammation and diagnosis of AA amyloidosis was 23 years. (Lane 2013) In this cohort, median age of onset of amyloidosis was 38 years with a 7-year-old with FMF as youngest patient.

Clinical features

Signs and symptoms of AA amyloidosis depend on the localization of the amyloid deposit. As a general rule, kidneys are the first and often only symptomatic organs in AA amyloidosis. Renal AA amyloidosis will be subclinical in most patients, with proteinuria as the sole manifestation. Progression of amyloid mass can lead to progressive proteinuria, decreased kidney function or nephrotic syndrome. If left untreated, end stage renal failure will eventually occur. Nephrotic syndrome or kidney failure may be the presenting symptom in patients with prior unrecognized auto inflammatory disease. This is usually due to underreporting of symptoms by these patients, presence of atypical symptoms or under-recognizing of inflammation by treating physicians; absolute absence of any signs of inflammation before development of AA amyloidosis is extremely rare or probably even non-existent. Even so-called “type II FMF” (FMF presenting with amyloidosis before typical signs and symptoms of FMF) is likely due to this mechanism.

The gastrointestinal system is the second most commonly involved. Intestinal AA amyloidosis is characterized by abnormal bowel movement, usually with diarrhoea, sometimes with constipation. Advanced intestinal AA amyloidosis leads to chronic malabsorption.

Involvement of other organs is very rare in AA type amyloidosis and is usually only seen in very advanced stages. Amyloid deposition in liver or spleen may lead to hepato- or splenomegaly or elevated liver enzymes. Cardiac amyloidosis may present as rhythm disturbances, myocardial infarction, heart failure or sudden death.

Diagnosis

As outlined previously, proteinuria is often the first and the most important sign of AA amyloidosis. Therefore, all patients with an auto inflammatory disease should be screened for the presence of amyloidosis at least yearly with a urinary protein evaluation. Proteinuria >0.5 grams per day indicates glomerular dysfunction and is an indicator for the presence of renal AA amyloidosis.

When proteinuria (or nephrotic syndrome or decreased kidney function) is present, a kidney biopsy should be considered to confirm the diagnosis of AA amyloidosis. Congo red staining of biopsy samples shows apple-green birefringence at polarized light microscopy. Immunofluorescence microscopy can prove the presence of amyloid A fragments in the biopsy specimens.

Screening for amyloidosis in other organs should only been done in the presence of amyloidosis-related signs or symptoms, as these organs are involved in patients with advanced amyloidosis.

Serum amyloid P (SAP) scintigraphy is only available in specialized centres. In this nuclear medicine technique the serum amyloid P component is radiolabelled with a radioactive isotope. Radiolabelled SAP localizes rapidly and specifically to visceral amyloid deposits and detects systemic AA amyloidosis with 100% sensitivity. (Hawkins Europ J Nucl Med 1995)

Prevention and treatment

AA amyloidosis used to be considered incurable. However, now that very effective anti-inflammatory treatment is available for auto inflammatory diseases, it has been shown that disease progression can be halted with adequate control of inflammation. In some cases, amyloid mass and organ dysfunction may even regress with adequate treatment. Goal of therapy is a serum SAA level <10mg/L. In patients with AA amyloidosis, it is recommended to perform regular measurements of serum SAA concentrations, even in the absence of inflammatory symptoms, since subclinical acute phase response can persist and should be avoided. SAA is the best marker to use; if SAA measurement is not available, CRP can be used as a surrogate.

Treatment of the auto inflammatory disorders is not discussed in detail here. In brief, in FMF, colchicine is the treatment of first choice. The usual effective dose is 1.5 to 2.0 mg daily. In patients with inadequate response or intolerance to colchicine, interleukin-1 (IL-1) inhibitors such as anakinra or canakinumab can be added to improve control of inflammation. Colchicine should be continued in all patients in the highest tolerable dose because it is the only drug with proven protective effect against AA amyloidosis in FMF.

In CAPS, TRAPS and MKD inhibition of IL-1 leads to stable disease or regression of amyloid mass in most patients with AA amyloidosis. (Lane 2013)

In patients with end stage renal failure dialysis or kidney transplantation may be necessary. After kidney transplantation strict control of inflammation is necessary to prevent recurrence of amyloidosis in the allograft. It is difficult to estimate the risk of recurrence of amyloidosis after kidney transplantation. Lane et al reported a subgroup of 13 patients with an auto inflammatory disease who had undergone kidney transplantation because of amyloidosis, with a median follow-up of 6.38 years. Amyloidosis recurred in 2 patients (15%) with graft survival of 6.08 and 17 years in these patients. (Lane 2013) Median time from diagnosis of amyloidosis to transplant was 4 years.

Even in patients with end-stage renal failure on dialysis, it is still relevant to control the inflammation. Reversion of lost kidney function is unlikely, but blocking progression of AA amyloidosis is still important to prevent other organ damage, especially gastrointestinal.

Patients with inadequate response to IL-1 inhibitors may be switched to interleukin-6 (IL-6) inhibiting therapy with the humanized IL-6 receptor antibody tocilizumab. Lane et al treated 14 patients with chronic inflammation and AA amyloidosis, who did not respond to other therapies, with tocilizumab. All 14 patients

had reduction of proteinuria. Regression or stabilization of amyloid depositions on SAP-scintigraphy was seen in 64% and 29%, respectively. (Lane 2015) Tocilizumab has also been shown to be effective in reduction of proteinuria and improvement of renal function in patients with amyloidosis secondary to rheumatoid arthritis. (Courties 2015) In a cohort with 11 patients with FMF, tocilizumab was effective in reducing proteinuria 73% of patients, (Yilmaz 2015) but serum creatinine decreased only in 45% of them.

Prognosis

Although studies are lacking, life expectancy for patients with auto inflammatory diseases seems similar to the general population when adequate control of inflammation is achieved. In patients with AA amyloidosis survival is impaired with a median survival of 19 years after diagnosis of amyloidosis (Lane 2013) – although this study primarily included patients in whom AA amyloidosis was diagnosed over 20 years ago, when fewer anti-inflammatory biologicals were available.

IN-DEPTH DISCUSSION II

Interleukin-1 inhibitors

The common pathogenic feature of autoinflammatory diseases is a consequent increased activity of the innate immunity, resulting in increased production of proinflammatory cytokines. Of these, interleukin-1 beta (IL-1 β) has been proven to be the most important factor that causes the clinical symptoms of autoinflammation, especially in the classical periodic fever syndromes. In some of the recently discovered rare autoinflammatory syndromes, the pathophysiological mechanisms of disease is different: for instance, hyperactivation of type-1 interferon signalling in proteasome disorders and of the IL-18/ γ -interferon pathway in NLRC4 related disease.

Pro-IL-1 β needs to be activated by multiprotein complexes called inflammasomes. Activation of inflammasomes leads to rapid conversion of pro- IL-1 β to the biochemically active mature IL-1 β . There are several types of inflammasomes activated by distinct stimuli and affected in different autoinflammatory diseases. The NLRP3 inflammasome is the best studied and is involved in the pathogenesis of CAPS. It is normally formed when inflammatory stimuli (bacterial compounds and other danger associated molecular patterns) are present. The NLRC4-inflammasome is physiologically involved in the detection of gram negative bacteria, whereas the pyrin inflammasome, involved in the pathogenesis of familial Mediterranean fever (FMF) and mevalonate kinase deficiency (MKD)

As IL-1 β is central to the pathogenesis of many autoinflammatory diseases, anti- IL-1- targeted therapy has been tried and found to be effective in an increasing number of autoinflammatory disorders .

Currently there are three IL-1 targeting drugs that are commonly used in autoinflammatory diseases.

The first widely used anti-IL-1 drug was anakinra (Kineret), which has been approved for clinical use in humans by the American FDA since 2001 and the European EMA in 2002. Anakinra is a recombinant form of the human IL-1 receptor antagonist. It blocks the biological action of IL-1 β and IL-1 α by competitive binding to the IL-1-type 1 receptor. Anakinra is available as subcutaneous injections, with a half-life of 4-6 hours, making daily subcutaneous injections necessary.

In most autoinflammatory diseases subcutaneous administration of anakinra leads to significant reduction of symptoms in 24-72 hours. Anakinra has been found to be safe and effective in both children and adults with different autoinflammatory diseases. The only placebo-controlled studies of anakinra in autoinflammatory disease have been in systemic JIA and in FMF. However, it has been shown in case series to effectively reduce the frequency, severity and duration of inflammatory attacks in cryopyrin associated periodic syndrome (CAPS), mevalonate kinase deficiency (MKD), Adult onset Still's disease, Schnitzler syndrome, TNF-receptor associated periodic syndrome (TRAPS). Anakinra is often used on a daily basis, in the standard dose of once daily 100 mg (adults) or 1 to 8 mg/kg (children). Younger children and those with severe inflammation tend to require higher doses. On demand therapy (i.e. anakinra is only started at the first signs of an inflammatory attack and is only continued for a few days) has been shown to be beneficial several cases of MKD and TRAPS.

Anakinra is generally so effective that it can also be used as a diagnostic tool: a quick clearly positive clinical response to anakinra points towards an IL-1 mediated autoinflammatory origin of the symptoms.

The major side effects of Anakinra are local pain at injection and transient local injection site reactions with subcutaneous infiltrates, which mostly occur during the second or third week of treatment. The exact mechanism behind these infiltrates is unknown and in most cases, they disappear during the next two or three weeks even when anakinra is continued. However, these local infiltrates can be extensive and painful and might form a reason to discontinue treatment in some patients. Other, less frequent side effects of anakinra are increased susceptibility to common infections (mostly skin and respiratory tract infections) and headache. Neutropenia and liver enzyme abnormalities have also been seen with anakinra. The incidence of opportunistic infections is rare; two cases of tuberculosis have been reported.

When subcutaneous anakinra leads to insufficient reduction of symptoms, a short course of daily intravenous infusion of 300 mg anakinra is safe in adults and could be helpful, although this approach is not scientifically proven.

To overcome the burden of daily, sometimes painful injections associated with treatment with anakinra, canakinumab (Ilaris®), a long acting anti-IL-1 β therapy, could be an alternative. Canakinumab is a humanized monoclonal antibody against IL-1 β and is thus able to directly bind to IL-1 β , preventing its biochemical action. Canakinumab has been approved for human use in the USA by the FDA since 2009 for the treatment of CAPS in both children >2 years of age and adults and for the treatment of systemic onset juvenile idiopathic arthritis (SoJIA), followed by approval by the EMA in Europe in the same year. In 2016, it was given a breakthrough designation for the treatment of MKD, TRAPS and colchicine-resistant FMF, based on preliminary study results and has now been registered for use in these indications as well as adult onset Still's disease in both the USA and Europe. Canakinumab has a half-life time of about 26 days, which translates in a dosing scheme of a single subcutaneous injection of 150 mg (adults) or 2-4 mg/kg (children) every two months in CAPS. Canakinumab is effective in reducing the frequency, duration and severity of inflammatory attacks in CAPS, TRAPS, MKD and colchicine resistant FMF and SoJIA and has also been effectively used in a limited number of patients with Schnitzler syndrome. However, the yearly dose needed in SoJIA, MKD, FMF and TRAPS tend to be higher than in CAPS. Unlike anakinra, canakinumab is associated with fewer local injection side reactions. Its major side effects are increased susceptibility to infections (mostly skin and respiratory tract), dizziness and abdominal pain. Canakinumab is very expensive at 5-10x the cost of anakinra.

A third available anti-IL-1 therapy is rilonacept (Regeneron). It has been approved for the treatment of CAPS since 2008 in the US and 2009 in Europe, but is not commonly used in the latter. Rilonacept is a dimeric fusion protein which consists of the ligand binding domains of the extracellular part of the human type 1 IL-1 receptor and IL-1 receptor accessory protein linked to the Fc portion of human IgG1. Rilonacept is able to bind

both IL-1 α and IL-1 beta and therefore prevents their biochemical action. It is available as subcutaneous injections which have to be injected every week due to its half life time of just over 7 days. The major side effects of rilonacept are local injection side reactions (erythema, bruising, pruritus, pain), increased susceptibility to infections (mostly respiratory tract) and headache. Placebo controlled studies have been performed in CAPS and colchicine resistant FMF only.

Off label use of IL-1 antagonists has been reportedly effective in an increasing number of disorders in which

Several new drugs targeting IL-1 are being developed and are likely to be introduced for common use in the next few years. Currently, the costs of IL-1 blockade are so high as to be unaffordable for patients in many countries. However, when disease cannot be controlled by NSAID's, steroids or -in the case of FMF- colchicine without intolerable side effects, there is sadly no effective alternative to IL-1blockade in IL-1 mediated autoinflammatory disease.

Few cases illustrate that the use of IL-1 targeting drugs during conception and pregnancy may be safe, but data is scarce and because of this it is advised that patients using IL-1 targeting drugs and considering getting pregnant should be counselled towards stopping IL-1 inhibitors.

Pain: mechanisms and management

Alexander So, Anthony Jones, Nadeem Jamal

A previous version was coauthored by Alexander So, Jiten Patel, Sylvie Revaz, Jean Dudler, Kay Brune, Haiko Sprott, Christian Roux, Silvano Adami, Emmanuel Biver

LEARNING OBJECTIVES

- Describe and explain the neurophysiological basis of nociception
- Differentiate between the different forms of nociception
- Describe and explain the mechanisms underlying inflammatory pain
- Describe and explain the pharmacological action of the principal drugs used in pain treatment
- Evaluate different forms of pain in a clinical context
- Describe and explain the multidimensional nature of pain in diagnosis and management of pain

1 Introduction

Previously thought to be a simple sensory experience, current literature suggests pain is a complex neuropsychological phenomenon. Its universality indicates that it has an important function to protect the organism from dangerous and noxious external events. In this sense, pain is protective, as it promotes avoidance of such harmful stimuli. It may even promote wound healing. However, when pain is the dominant symptom in a clinical setting, provoking suffering and incapacity, it is termed 'bad' or 'maladaptive'. This state may be called 'pain disease'. Pain is often classified into acute and chronic states. Acute pain, usually refers to short-lived, protective pain as described above, whereas chronic pain is maladaptive and can lead to disability. However, this is an oversimplification as pain is often a combination of chronic and recurrent acute pains and is rarely a single consistent experience.

In the context of scientific study and medical treatment, it is important to define pain and its underlying mechanisms as well as how it is perceived (nociception). The International Association for the Study of Pain (IASP) (1979) defines pain in the following terms: *"An unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage."* Pain is also described as a subjective experience in which an individual's past experiences partly determine the current experience of pain. Functional imaging has revealed that pain also has a strong association with emotional state and is described often in terms of 'suffering'. It is beyond the scope of this chapter to cover the entire extent of these influences, but it is important for the clinician to be aware of these influences in the evaluation of the patient's symptoms and in the elaboration of a management plan. In 1999, Ronald Melzack coined the term 'neuromatrix of pain' to suggest the processing of pain that occurs in the higher cortical centres. Melzack combined the biopsychosocial experience of pain and hypothesized the interactions of neural mechanisms of pain perception (Melzack, 1999). In summary this states that the brain has the job of integrating neural information coming from the body with prior experiences of pain, including emotions, into one experience. Since then, clinicians have recognized the success of using an integrative approach to the management of pain.

In rheumatology, pain is the most common presenting complaint of our patients. Often it is accompanied by overt physical manifestations of disease, affecting the articular and non-articular connective tissue. It may also be a major clinical symptom in the absence of obvious, defined pathological abnormalities, such as in fibromyalgia, or when the pathological source of nociceptive stimulation is not easily delineated, as in chronic regional pains such as low back pain. In a majority of patients complaining of chronic pain in general practice there is no clearly definable physical cause (Rajapakse 2014). The management of such pain is an increasing problem for clinicians as approximately 40% of patients felt that their pain was managed inadequately in a survey published previously (Breivik et al, 2006). Furthermore, recent studies show that conventional treatments for pain, such as paracetamol and opiates, may have low efficacy for chronic pain and in fact may

not be worthwhile in these patients due to the troublesome side effects (Shaheed et al, 2016, Roberts et al, 2015). Therefore, to better understand the concepts underlying pain and its management, this chapter will cover our current understanding of the neurophysiological mechanisms underlying nociception, the clinical manifestations of different types of pain, as well as the biopsychosocial approach to the management of pain.

2 The neuroanatomy of pain

The common pathway of all pain perception is the transmission of neuronal signals from peripheral sensory organs/preterminal nociceptor to the spinal cord where synaptic processing occurs. The signals are then transmitted along the spinothalamic and spinoparabrachial pathways to higher centres in the somatosensory cortex (anterior cingulate cortex, pre-frontal cortex), after passing through the thalamus where the sensation of pain evokes behavioural, physiological, and emotional/affective responses.

2.1 Nociceptors and nociception

Nociception—the detection of tissue damage and the process that transforms the triggering stimulus to neural signals—is mediated by the generation and transmission of electrical signals from peripheral nerve terminals along unmyelinated C-fibres and thinly myelinated A δ fibres when they are activated by receptors which are sensitive to either heat, cold, protons, or mechanical stimuli. It is important to clarify the terms hyperalgesia, hypersensitivity and allodynia as these are used frequently in this chapter. Hyperalgesia refers to increased pain response to a noxious stimulus. Hypersensitivity, in pain, is defined as increased neuronal activity due to a non-noxious stimulus. Allodynia is a painful response to a non-noxious stimulus.

Multiple nociceptive receptors are found in these peripheral nerve endings and they can act singly or in collaboration to mediate a particular painful sensation (figure 1). In general, these receptors are non-selective cation channels that are activated by physico-chemical changes and not by electrical alterations of the cell membrane. Once activated, they open to allow sodium and calcium ions to flow into the nerve terminal, producing an inward current that depolarises the membrane. The receptors of the transient receptor potential (TRP) family, which includes the capsaicin receptor (responding to chilli pepper) (TRPV1), are one example that have been studied in detail. The TRPV1 receptor was the first to be cloned and led to the subsequent identification of others within this receptor family. They have a common structure possessing six transmembrane domains and function as ion channels on specific stimulation. As summarised in table 1, the expression of these receptors is not restricted to neural tissue and TRPV1 is found in other tissues such as neutrophils and mast cells. However, their high level of expression in nerves and the experimental behavioural evidence from mice with deletions of specific receptors strongly support their different roles in nociception (reviewed in Levine and Alessandri-Haber, 2007).

Other receptors are the sensory neuron-specific acid gated ion channel ASIC (acid sensing ionic channel) (Waldmann et al, 1997) and the ATP-activated ion channel P2X. They are found on sensory neurons and contribute to nociception when cells are damaged to release intracellular ATP (Cook and McCleskey, 1997).

Neurokinins are neurologically active peptides known to facilitate mechanisms of inflammation and pain. Substance P was the first peptide to be shown to be specific for small sensory afferents and belongs to a family of small neuropeptides that include neurokinin A. Approximately half of C fibres and 20% of A δ fibres are estimated to contain substance P. It acts through the NK (natural killer) family of receptors that are most abundant on dorsal horn neurons. Experiments showed that, when activated, these receptors facilitate hyperalgesia.

Figure 1 Nociceptors found on sensory nerve endings that mediate painful stimuli. Different nociceptors respond to distinct stimuli to trigger receptor activation and transmission to the afferent neuron. The transient receptor potential (TRP) family includes multiple members that are activated by physical or chemical stimuli to produce an afferent signal. The sodium channel Nav1.8/1.9 is located at the nerve endings and modulates the threshold of activation of the nerve.

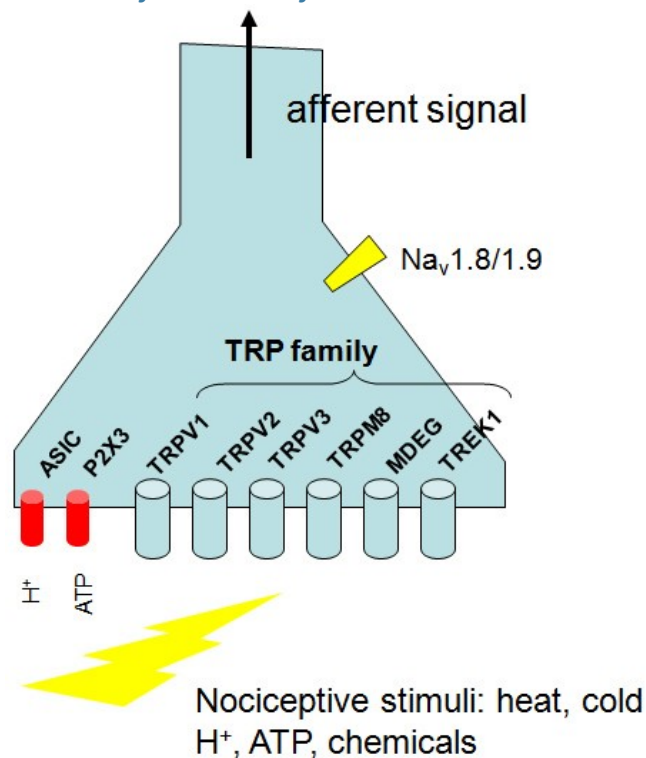

Table 1 The TRP family of nociceptors

Name	Agonists	Expression
TRPV1	Vanilloid compounds (capsaicin) Camphor, NO Moderate heat (>43°C)* Low pH (<5.9)	DRG Mast cells, keratinocytes Bladder epithelium, brain
TRPV2	High temperature (52°C)	DRG, Aδ fibres
TRPV3	Warm temperature (>34°) Repetitive heat stimulation Thyme, cloves	DRG, brain, skin (mice), spinal cord
TRPV4	Hypotonicity Heat >27°C Low pH Endocannabinoids	Cochlear cells DRG Cutaneous Aδ and C fibres
TRPA1	Cold (8–26°C) Menthol, eucalyptol	DRG
TRPM8	Mustard oil, garlic Ginger	Inner ear, DRG

**Prostaglandins increase the sensitivity of this receptor by lowering the activation temperature to ~37°C. DRG, dorsal root ganglion; NO, nitric oxide; TRP, transient receptor potential.*

2.2 Peripheral neurons

Action potentials are generated at the peripheral endings of nociceptive nerve fibres embedded in the tissues in response to the appropriate nociceptive stimulus to be transmitted centrally. The locations of these nerve endings include superficial structures such as the skin, cornea, and mucosa as well as internal structures such as the joint, muscle, and pericardium. Some tissues that do not have pain innervation are cartilage and bony matrix (as opposed to the periosteum).

Anatomically, there are two broad groups of sensory fibres: myelinated A fibres and unmyelinated C fibres. Most small diameter cutaneous sensory fibres (type Aδ or C) are nociceptive, with the majority of type C fibres being polymodal (responding to several forms of noxious stimuli such as heat, cold, mechanical pressure, and chemicals). Type Aδ fibres, being myelinated, are more rapid (conduction velocity of 2–30 m/s). In contrast, type C fibres are of small diameter (0.2–1.5 μm), unmyelinated, and therefore transmit their information slowly (≤2 m/s). Due to their faster conduction and less diffuse receptive fields, Aδ fibres are responsible for conduction of sharp pain, while type C fibres respond to multiple nociceptive signals and are responsible for the sensation of ‘burning’ or ‘aching’ pain.

2.3 Spinal cord

Peripheral sensory neurons transmit their signals along nerve fibres to nerve terminals in the dorsal horn of the spinal cord. The cell bodies of these peripheral neurons are located in the dorsal ganglia and trigeminal

ganglion (for the face). In the spinal cord, afferent nerve terminals transmit their signals to ascending neurons that project to the brain, either in a monosynaptic connection or through a network of interneurons. Interneurons can have excitatory as well as inhibitory properties (figure 2). Interneuronal networks transmit nociceptive information and also modulate that information and pass it on to other spinal cord neurons, including flexor motor neurons and nociceptive projection neurons—for example, certain patterns of stimulation can lead to enhanced reflex actions and to sensitisation of projection neurons and increased nociceptive transmission. Other inputs result in the inhibition of projection neurons. The balance of these excitatory and inhibitory processes is the basis of whether information is presented to the brain as nociceptive or not and will partially determine how it is perceived (formerly gate control) (Melzack and Wall, 1965).

2.4 Spinal cord transmission

Glutamic acid is an amino acid and the most abundant excitatory neurotransmitter in the nervous system. Glutamate is released from the spinal cord during peripheral nociceptive stimulation of small afferent neurons, and it acts on specific receptors on spinal neurons. These receptors include the α -amino-3-hydroxyl-5-methyl-4-isoxazolepropionic acid (AMPA), kainate, and N-methyl-D-aspartate (NMDA) receptors. The AMPA receptor is an ion channel and is found in high concentrations in the dorsal horn and is probably the main mechanism of synaptic transmission in the dorsal column.

2.5 Projection neurons

Nociceptive projection neurons transmit information to a number of regions of the brainstem and diencephalon (Willis and Westlund, 1997). Some of these projections are discussed in more detail.

2.5.1 Spinothalamic tract

Based initially on clinical studies of spinal cord damaged patients and subsequently confirmed in experimental studies in animals, the spinothalamic tract conveys the sensations of pain, cold, warmth, and touch. Animal studies showed that most of the spinothalamic neurons project to the contralateral thalamus, but a small fraction projects ipsilaterally. The cells of origin are concentrated in laminae I and V of the spinal cord dorsal horn, their axons crossing the midline in the ventral grey commissure and then ascending in the ventral and in the ventrolateral quadrant. After passing through the brainstem, the axons terminate in the lateral thalamus (figure 2).

Figure 2 Neuroanatomy of pain projections. CGRP, calcitonin gene-related peptide; SP, substance P. (Reproduced with permission from Hunt and Mantyh, *Nat Rev Neurosci* 2001;2:83–91.)

2.5.2 Spinomesencephalic tract

The spinomesencephalic tract includes several projection systems that terminate in different areas in the midbrain. The cells of origin of the spinomesencephalic tract are distributed in the spinal cord in a manner similar to that of the cells of origin of the spinothalamic tract, derived largely from neurons in the dorsal horn, and terminate in the parabrachial and periaqueductal grey matter. This tract has also been termed the spinoparabrachial tract. Neurons in these areas in turn project into forebrain regions such as the hypothalamus and amygdala. These areas are capable of modulating the affective dimensions of pain and controlling autonomic activity (Hunt and Mantyh, 2001).

2.5.3 Thalamus

Axons from the spinothalamic tract synapse at 3 different regions within the thalamus: posterior thalamic nuclei, intralaminar and ventral posterior lateral thalamus (VPL) (Millian, 1999). The posterior nuclei and VPL share somatotopic connections with the primary somatosensory cortex, thereby suggesting that it's associated with the localisation of pain stimulus. Neurons from the intralaminar nuclei synapse in various areas of the limbic system. This suggests that these connections are predominantly concerned with the affective-

motivational component of pain. The spinothalamic tract projects to the brain stem reticular formation and then to the thalamus. These connections extend to the cortex from the thalamus.

2.5.4 Cerebral cortex

Recent evidence from mainly functional brain imaging studies supports the view that various cortical and subcortical structures including medial prefrontal cortex, anterior cingulate cortex (ACC) and insular cortex participate in pain perception. These areas are collectively termed 'pain matrix'. Animal studies have shown responses to nociceptive stimuli in cortical neurons, and imaging studies have demonstrated pain-associated responses in a number of cortical areas. Indeed, functional imaging of the brain using positron emission tomography (PET), functional magnetic resonance imaging (fMRI) and electrophysiological (EEG and magnetoencephalography) techniques have provided novel insights of brain activation in a number of painful states (eg, arthritis, neuropathic pain, fibromyalgia) (Tracey, 2008). A meta-analysis from human studies showed that the S1 and S2 cortical regions, insular, ACC, the prefrontal cortex, and the thalamus were activated during pain (Apkarian et al, 2005). Other regions, such as the basal ganglia, cerebellum, amygdala, hippocampus, and areas within the parietal and temporal cortices, can also be activated, depending upon the particular set of circumstances for that individual. The contextual associations of these areas are described below.

Figure 3 (Jones 2012) shows connections between areas collectively known as the human pain matrix. IC = insular cortex, SI SII = primary & secondary somatosensory cortex, ACC = anterior cingulate cortex, PFC = prefrontal cortex.

As simplified in figure 3, the somatosensory cortex is associated with the lateral component of the pain matrix. This pathway is concerned with the sensory- discriminative component of pain. This includes the quality (burning, stinging, stabbing etc.), intensity and location of the pain. These are facilitated by connections between the lateral thalamus, posterior insular cortex and somatosensory cortices (SI and SII) (Kulkarni et al. 2002). The medial pathway is concerned with the affective-motivational processing of pain. This includes the computing of the emotional and unpleasantness experience attached to pain. These processes are facilitated by neurons between the medial thalamus, ACC and insular cortex. This pathway also mediates the response aspects of pain such as prediction, learning, attention, avoidance and anticipation of pain. These are a result of connections that exist between the medial thalamus, prefrontal motor cortex and brain stem structures such as the periaqueductal grey area.

2.5.5 Limbic structures

Pain is often accompanied by motivational-affective and autonomic responses, such as an increase in the heart rate and blood pressure, endocrine changes, increased attention, arousal, anxiety, and emotional distress (suffering). The neural pathways that mediate these changes consist mainly of projections from the intralaminar nuclei, from the thalamus, and the reticular formation to the limbic system (hypothalamus, amygdala, and anterior thalamic nuclei).

3 Neurobiology of pain

Much of our current understanding of pain has developed from the studies of Melzack and Wall, who laid the groundwork for an integrative approach to the neurobiology of nociception. We distinguish two distinct aetiological causes of painful sensations—nociceptive (tissue damage-related) which may or may not have an inflammatory component and neuropathic (nerve damage related) (figure 4)—that can be characterised by their clinical manifestations as well as their underlying neurobiological processes. Some authors have suggested a third category—functional pain that describes a painful sensation in the absence of an identifiable nociceptive stimulus (Woolf, 2004*). We also recognise increasingly that pain is not only associated with injury and inflammation, but can be modified by cognitive factors which influence the brain's processing of the sensory information - such as fear of damage, psychological distress (anxiety and depression) and catastrophising (Vogt 2005).

Figure 4 Different modalities of nociception. ATP, adenosine triphosphate; Cox2, cyclo-oxygenase 2; DRG, dorsal root ganglion; NMDA, N-methyl-D-aspartate; TNF α , tumour necrosis factor α . (Reproduced with permission from Scholz and Woolf, *Nat Neurosci* 2002;5:1062–7.)

3.1 Inflammatory pain

Nociceptor function is substantially modified in response to tissue damage, inflammation or injury to the nervous system, by altering the threshold and transmission properties of the sensory neurons. This modulation causes peripheral sensitisation (see below) and explains the clinical phenomenon of hyperalgesia (or hypersensitivity). In molecular terms, inflammatory mediators such as bradykinins and prostaglandins are capable of modifying the sensory neuron's threshold of activation by phosphorylation of ion channels and receptors causing peripheral sensitisation, a state of increased sensitivity to stimuli (figure 5). One of the best studied mechanisms is that of the prostaglandins, with prostaglandin E₂ (PGE₂) and prostaglandin I₂ (PGI₂) being the most relevant to nociception. The synthesis of prostaglandin metabolites from arachidonic acid is mediated by the cyclo-oxygenase enzymes COX-1 and COX-2 that can be upregulated in inflamed tissues. Prostaglandins signal through their specific receptors (the IP and EP1–4) that are present not only on peripheral sensory neurons, but also in the dorsal ganglia (see section on central processing of pain) (Zeilhofer and Brune, 2006*). Signalling leads to activation of intracellular kinases (protein kinase A (PKA) and protein kinase C (PKC) in particular) that phosphorylate ion channels in nerve endings to alter their reactivity. Inflammatory cytokines such as interleukin 1 β (IL-1 β) and tumour necrosis factor α (TNF α) also modulate pain perception and reduce the threshold of painful stimuli (Oprea and Kress, 2000). They are capable of inducing COX-2 expression that in turn leads to increased prostaglandin production, and hence explain some of the analgesic effects of non-steroidal anti-inflammatory drugs (NSAIDs) in conditions such as rheumatoid and osteo-arthritis.

Figure 5 Inflammatory mediators induce peripheral sensitisation. Inflammatory mediators, such as bradykinin and prostaglandin E₂, act through their receptors to modify terminal protein kinase C activity and the conductance of the sodium channel, resulting in lowering of the activation threshold of the TRPV1 receptor. TRP, transient receptor potential.

3.2 Neurogenic inflammation

Neural networks and inflammatory mediators interact bidirectionally and there is accumulating evidence that neurotransmitters can influence the inflammatory and immune response in experimental models. In man, the most clinically striking example is the reduction of synovial inflammation on the affected side of a rheumatoid arthritis patient who has suffered a stroke. Neuropeptides such as substance P and calcitonin gene related peptide (CGRP), released from peripheral nerve endings located in the joint, can have pro-inflammatory effects in arthritis, and their activity is regulated by neuropeptidases that inactivate them (reviewed in Schaible et al, 2005*). Furthermore, there is evidence that vagal nerve stimulation and release of acetylcholine has an anti-inflammatory effect mediated by its binding to specific cholinergic receptors on monocytes and macrophages (Tracey, 2009).

3.3 Neuropathic pain

Peripheral neuropathic pain may be caused by traumatic or compression peripheral nerve injury, peripheral neuropathy in metabolic conditions such as diabetes, nerve damage resulting from viral infections such as herpes zoster and rarely inflammatory conditions such as vasculitis, or lumbar radiculopathy due to a herniated lumbar or cervical disc are some examples of neuropathic pain caused by lesions of the peripheral nerve(s). Central neuropathic pain may occur in association with lesions of the spinal cord or the brain and is more commonly associated with sensory deficit (particularly pin-prick, heat and pinch). This may be caused by any kind of damage anywhere in the central nervous system but is more common with lesions of the pain system (spinothalamic tracts and pain matrix) and is most commonly caused by stroke and MS. Patients can experience either spontaneous pain or have symptoms of hyperalgesia or allodynia (painful sensation provoked by a normally innocuous stimulus such as light touch) within the territory of the neurological deficit. Cerebrovascular disease is increased in patients with inflammatory arthritis and post-stroke shoulder pain is present in approximately 50% of patients who have a stroke within the first six months. In those who receive prompt therapy for impingement (steroid injection) and nocturnal pain (low dose amitriptyline or gabapentin) the prognosis is reasonably good with approximately 70% resolution at six months. It is not clear why certain patients experience neuropathic pain and others not with similar lesions but peripheral and central sensitization is a common feature. Post-stroke shoulder pain is associated with changes in opioid receptor binding within the pain matrix.

4 Drug targets in the spinal and supraspinal neurotransmitter/receptor system

4.1 Opioids

Opioid receptors have a major role in the processing of nociceptive information in the periphery, the spinal, and supraspinal levels. Although opioid receptors were first characterised pharmacologically as mediators of

the analgesic effect of morphine and its derivatives, their presence in the nervous system indicates that they must have endogenous ligands. The first endogenous ligand that could be identified was enkephalin; now ligands for opioid receptors include β -endorphin, dynorphin, and the enkephalins, a family of peptides that are generated following processing of their respective precursors: proopiomelanocortin, prodynorphin, and preproenkephalin. Their binding to different opioid receptors mediates their actions, which are summarised in table 2. The fourth receptor is the so-called nociceptin receptor (also called ORL-1). It binds the endogenous peptide nociceptin and differs from other known receptors in that it is not antagonised by naloxone, a selective receptor antagonist.

Table 2 Classification of opioid receptors

Name	Endogenous agonists	Effects	Exogenous agonists	Antagonist
MOP-R (μ)	β endorphin enkephalins	Analgesia, respiratory depression, constipation, euphoria	Morphine	Naloxone
DOP-R (δ)	Enkephalins		Deltorphin	Naloxone
KOP-R (κ)	Dynorphins	Sedation, dysphoria	Enadoline	Naloxone
Nociceptin receptor (OPL-1)	Nociceptin	Anxiety, depression	Buprenorphine	

Opioid receptors are G-proteins with a typical seven transmembrane domain organisation and an extracellular binding site for its ligands. Receptor occupancy leads to modulation of K^+ and Ca^{2+} channels and a decrease in neuronal excitability. Opioids are generally recognised to inhibit neuronal activity. The location of the receptor in a neuronal circuit determines its effects. If the receptor is located presynaptically, it will inhibit neurotransmitter release. If located on the post-synaptic neuron, it will reduce neuronal firing. Furthermore, the nature of the neuron on which the receptor is sited influences the final effect. If the opioid receptor is located on an inhibitory neuron, it may have a paradoxical effect, leading to excitation. This is thought to account for effects such as vomiting and behavioural changes.

The different subclasses of opioid receptors are widely expressed on neuronal as well as non-neural tissues. They account for the analgesic effects of opioids as well as central side effects such as nausea, vomiting, respiratory sedation, and dependence. In addition, expression of opioid receptors in other tissues, such as the oculomotor nucleus and the smooth muscle of the gut, account for the side effects such as pupillary constriction and, for example, constipation encountered with opiate therapy. Recently, PET imaging using specific opioid receptor ligands has depicted the brain regions that are activated in different pain states (Henriksen and Willoch, 2008) providing evidence of release of endogenous opioids during pain and placebo analgesia. Moreover recent studies have identified adaptive increases in opioid receptor binding within the

pain matrix associated with increased resilience to pain (pain threshold and tolerance) in patients with arthritis (Brown et al 2015).

4.2 Catecholamines

Noradrenaline and adrenaline are released in the spinal cord when descending neurons (from the brain stem and diencephalic structures) are stimulated. They act through the classical adrenergic receptors ($\alpha 1$ and $\alpha 2$) located in the dorsal root ganglia and the dorsal horn, and modulate spinal afferent and efferent activity. In experimental systems, intrathecal injections of noradrenaline produced a potent analgesic effect in rats and in primates that is mediated primarily by the $\alpha 2$ receptor.

4.3 γ -Aminobutyric acid/glycine

γ -Aminobutyric acid (GABA) and glycine are the principal inhibitory neurotransmitters in the spinal cord, acting through their respective receptors. Activation of these receptors leads to an increase in chloride conductance and stabilisation of the transmembrane potential leading to reduced neuronal excitability. These inhibitory effects serve to reduce the transmission of nociceptive information in projecting neurons. It is postulated that benzodiazepines that augment the action of GABA reduce nociceptive reflexes in animals. However, there is no clear evidence of benzodiazepines being analgesic in humans.

4.4 Cannabinoids

Cannabinoid receptors (CB1 and CB2) are widely expressed in the brain and spinal cord as well as the peripheral nervous system. Their endogenous ligands are called endocannabinoids, of which anandamide is the prototype. At the physiological level, cannabinoid receptor signalling leads to inhibition of Ca^{2+} channels on both excitatory and inhibitory neurons in the spinal cord and elsewhere, and local delivery of CB agonists (to nociceptive neurons), thus producing an antinociceptive effect. However, a recent systematic review concluded that, based on current randomized control trial evidence, cannabinoids have no role in acute pain management (Stevens and Higgins 2017).

4.5 Cholinergic drugs

Acetylcholine and the cholinergic receptors (muscarinic and nicotinic) have been characterised in the spinal dorsal horn. The effects of cholinergic signalling on nociception are largely mediated by its secondary actions on glutamate, GABA, and noradrenaline receptor systems. They have been reported to have analgesic effects in selected animal models.

5 Pain mechanisms in rheumatic diseases

Rheumatic diseases commonly present with pain as a major symptom, typically involving articular and periarticular structures. In inflammatory arthritides such as rheumatoid arthritis or gout, clinical signs of inflammation are usually obvious and are commonly accompanied by systemic changes in inflammatory parameters. In degenerative arthritides such as osteoarthritis the sources of pain include the periosteum as well as low grade synovitis. The source of pain is more difficult to pinpoint in the spine, where nociceptive, neuropathic and psychological mechanisms are probably all involved in different forms of spinal pain. The situation is even more complicated in chronic pain states where there is evidence that neuroplasticity can play a role in the perpetuation of chronicity.

5.1 Inflammatory pain

A large number of factors released at the site of inflammation elicit pain when injected into peripheral tissues, either by reducing the threshold of nociceptor activation or by increasing the responsiveness of the nociceptor to suprathreshold stimulation. Of particular relevance to rheumatological pain syndromes are the roles of bradykinins, prostanoids, and cytokines, though other pathways such as protease activated receptor-2, histamine, and nitric oxide (NO) are also known to be involved.

5.1.1 Bradykinin

Bradykinin, a 9-amino acid peptide, is released from its precursor protein high molecular weight kininogen by the action of the protease kallikrein that is produced and released at the sites of inflammation or tissue damage. Upon binding to the B2 receptor, bradykinin activates sensory neurons via PKC-dependent pathways to sensitise the TRPV1 ion channel. The activity of bradykinin is terminated upon its degradation by the action of kininases that include angiotensin converting enzyme and aminopeptidase P.

5.1.2 Arachidonic acid derivatives

The generation of prostaglandins, in particular PGE₂, PGI₂ and PGD₂, from arachidonic acid by the action of the cyclo-oxygenases COX-1 and COX-2 plays a key role in inflammatory pain. COX-2 is not constitutively expressed in peripheral tissues (with the exception of the kidney and the brain), but is rapidly induced in cells such as macrophages, monocytes, and synoviocytes when they are exposed to inflammatory stimuli. The prostaglandins that are generated sensitise peripheral neurons to noxious chemical, thermal, and mechanical stimuli (see below, figure 6).

Interestingly, COX-1 and COX-2 are also expressed in the spinal cord and contribute to modulating nociception by the action of prostaglandins on prostanoid receptors that are expressed in DRG neurons. Part of the analgesic effect observed clinically during therapy with NSAIDs is explained by this central inhibition.

5.1.3 Cytokines

Proinflammatory cytokines modulate nociception peripherally by the induction of molecules such as cyclooxygenases (COXs) (see above) and by acting directly on sensory and central neurons. The best studied cytokines are IL-1 β and TNF α , but IL-6 and leukaemia inhibitory factor (LIF) have also been implicated. The administration of small doses of TNF α in the mouse footpad induced hyperalgesia and an effect on neuronal transmission was also demonstrated (Hori et al, 1998; Schafers and Sorkin, 2008). In addition to direct neuronal effects, IL-1 β and TNF α also modulate the secretion of cytokines by glial cells and act as an additional modulator of central pain perception (Hess et al, 2011*). Recent clinical trials are targeting nerve growth factor (NGF) in chronic pain patients. Several humanized anti-NGF monoclonal antibodies have produced significant pain relief in patients with osteoarthritis leading to functional improvements. However, there is no evidence to suggest effectiveness of anti-NGF monoclonal antibodies in neuropathic pain. Studies have also shown significant side effects related to these antibodies such as worsening of peripheral neuropathy and joint destruction in some patients. Due to this, the clinical trials were halted by the Food and Drug Administration (FDA). However, since then the FDA have lifted this hold and clinical trials for these drugs have restarted (Bannwarth and Kostine 2014).

5.2 Complex regional pain syndrome

Also known as algoneurodystrophy, complex regional pain syndrome (CRPS) contains features of both nociceptive and neuropathic pain. Two subtypes are recognised (see chapter on 'Regional pain syndromes'), and in CRPS type II, allodynia, hyperalgesia as well as vasomotor and cutaneous changes are common clinical features. These develop after nerve injury, and may persist for months or even years. It has been suggested that following injury, an aberrant tissue response associated with neuronal changes at the peripheral or dorsal horn level are at the basis of clinical symptoms (Marinus et al, 2011*).

5.3 Chronic pain

Chronic musculoskeletal pain poses a particular challenge in terms of diagnosis and treatment. In some cases, a clearly identifiable pathological cause can be found, but in many cases, the origin is either unclear (as in fibromyalgia) or it is extremely difficult (with the means currently available) to identify the exact structures that provoke nociception (eg, chronic low back pain). As discussed earlier, 'plasticity' or modification of neural pathways, either at the nerve terminal or in neural networks in the spine and the brain, can take place after an initial nociceptive stimulus, resulting in an altered threshold to subsequent stimuli or even give rise to spontaneous pain. Another additional factor is the cognitive/affective component as chronic pain can lead to psychological or affective changes that resemble depression. The question often raised is whether these affective changes precede the painful state, and whether the pain is of psychological origin. Psychological

distress is a risk factor for developing chronic widespread pain and psychological interventions are helpful once it is established (McBeth 2001).

5.4 Fibromyalgia: an example of functional pain

Fibromyalgia or chronic widespread pain is probably one end of a spectrum of somatoform pain disorders which range from chronic regional pain (irritable bowel syndrome, atypical facial pain, headache) to chronic widespread pain. These all tend to be associated with sleep disturbance, multiple symptoms and consulting, psychological distress and endocrine disturbance (endometriosis). It is a good example of functional pain, as opposed to the other aetiological categories detailed above. Recent neurophysiological and functional imaging studies implicate central sensitisation as a possible mechanism for the chronic perception of pain in the absence of obvious pathology. Testing showed a reduced threshold to cold pain in comparison to normal subjects (Desmeules et al, 2003) and enhanced activation of certain cerebral areas in fibromyalgia patients (Gracely et al, 2002), giving rise to the theory that central processing pathways are altered in fibromyalgia. The precise brain mechanisms are still unclear but recent studies have shown that in patients with fibromyalgia there is abnormal processing of pain expectation. This is associated with increased processing of pain expectation within the insula cortex, which is concerned with the emotional processing of pain, that is correlated with the extent of pain and tenderness. There is a corresponding reduction in processing of expectation within the dorsolateral prefrontal cortex that is inversely correlated with abnormal coping such as catastrophising (Brown et al 2013). Interestingly, similar findings were found in patients with chronic arthritis pain suggesting there may be common central mechanisms for more localized and widespread pain. However, the question of the role of depression in this disorder and how it can affect central pain processing is still not entirely resolved. However, when patients are given an eight week course of mindfulness-based cognitive therapy for their pain the unpleasantness of the pain, psychological distress and abnormal expectation-processing are all significantly improved (Brown et al 2003).

5.5 Depression and pain

The prevalence of major depression as a comorbid factor in chronic pain conditions is highly variable, depending on the underlying painful pathology. For example, in a study of chronic low back pain, depression was found in 72% of the subjects in a small study (Gallagher et al, 1995), while in a study on chronic pain, depression was present in 18%, compared to a prevalence of 8% in the general population (Magni et al, 1990). Although there is a certain 'chicken and egg' dilemma in determining if one preceded the other, it is well known that in chronic diseases with pain as a major symptom, depressive symptoms are frequently reported (Kroenke and Price, 1993) and are a risk factor for developing chronic widespread pain (McBeth 2001, MacFarlane 2001). Practically both drug and non-drug therapies for depression are effective for chronic pain and it is difficult to manage pain without active management of the depression.

6 Mechanisms of neuronal modification

6.1 Central mechanisms

6.2.1 Neuroplasticity and pain

The early concepts of the neurobiology of pain concentrated on transmitter/receptor mechanisms and the different neuronal connections that mediate nociception. Recent research has highlighted that these connections are not stable, but depend on dynamic processes that modify the circuits of neural transmission—hence the term plasticity. Many studies have concentrated on the modulation of neurotransmission at the spinal level, but there is also evidence to show that neuroplasticity can occur at a higher level that may explain the interactions between cognition, behaviour, and pain perception, which are frequently observed in clinical practice.

6.1.2 Top-down modulation and alpha waves

One of the commonest frequencies of brain waves is alpha waves (8-12Hz). Early investigations showed that alpha waves are associated with an idle resting state, as alpha increases when an individual closes their eyes and no stimulus is provided. However, more recent theories suggest that alpha waves represent a gating mechanism in the brain, specifically that alpha waves are emitted when the brain inhibits regions that are not relevant to the specific task an individual is currently focused on. This may be a method of streamlining information transfer and increasing efficiency. Further evidence suggests that alpha waves specifically from the frontal regions of the brain (frontal alpha) show an increase in power during top-down modulation of incoming stimuli. Studies have shown increases in frontal alpha after placebo administration which led to reduced nociception in patients. A more recent study by Ecsy et al. also showed that alpha waves can be trained to modulate the perception of pain (Ecsy et al, 2016). In this experiment, participants were given auditory and visual stimuli at 3 different alpha frequencies (8, 10 and 12Hz). These participants, compared to controls, reported a significant reduction in pain ratings which were independent of other factors recorded in the study. Although still in the early stages, this shows that alpha wave entrainment is possible and could be a potential treatment method in the future.

6.2 Peripheral sensitisation

Nociception can be modulated by tissue damage or inflammatory mediators (bradykinin and PGE₂) or chemicals released from damaged cells (ATP, H⁺ ions). These agents sensitise the nociceptor so that the activation threshold is lowered. In the case of PGE₂, binding to its receptor leads to activation of intracellular protein kinases that in turn are able to alter the activity of receptors as well as ion channels. For example, the TRPV1 channel is normally activated at around 42°C, but when phosphorylated, its threshold of activation is reduced to near normal body temperatures. Furthermore, sensitisation is facilitated when ion channels (in

particular sodium channels) that are exclusively expressed on nociceptors are activated by phosphorylation, resulting in an increase firing of the nociceptor, generating more action potentials (figure 5).

6.2.1 Wind up

‘Wind up’ describes the phenomenon whereby the action potential output from the dorsal horn neuron increases progressively on repeated low frequency nociceptive stimulation. Biochemically, repetitive stimulation leads to the co-release of substance P with the transmitter glutamate, resulting in activation of cation channels and a prolonged postsynaptic depolarisation lasting tens of seconds. In humans, an example of this phenomenon is the increase of perceived pain when a subject is stimulated repeatedly with heat stimuli of the same intensity.

Figure 6 Prostaglandin E₂ (PGE₂) facilitates central sensitisation. (A) PGE acting through prostaglandin receptors modifies sodium channels (Nav1.8, 1.9) and nociceptor threshold to facilitate nociceptive signalling. (B) PGE acts on the post-synaptic neuron to increase GABA and glycine induced signalling. GABA, α -aminobutyric acid. PKA, protein kinase A. (Reproduced with permission from Jones et al, Br Med Bull 2003;65:83–93.)

6.2.2 Central sensitisation

Similar to the processes already outlined in peripheral sensitisation, central neurons (located in the dorsal horn of the spinal cord) can be sensitised. The results of central sensitisation are the amplification and facilitation of synaptic transfer of signals to dorsal horn neurons. An example for amplification is the ability of a usually subthreshold stimulus to activate the dorsal horn neuron after the neuron has been conditioned by a brief and intense nociceptive stimulus. Facilitation is the term that describes the increase in synaptic

transmission in response to a stimulus that did not originate from the nociceptor, such as to a low threshold mechanoreceptor. The clinical correlates of sensitisation and facilitation are the phenomena of hyperalgesia and allodynia.

A key receptor that mediates this effect is the glutamate-activated NMDA receptor. During central sensitisation, receptor phosphorylation leads to increased expression of the NMDA receptor on the synaptic membrane and hence its response to glutamate. The resultant increase in receptor responsiveness to glutamate increases cellular excitability. This means that it can be activated by signals that are normally below the threshold of activation (figure 7). Inhibition of the NMDA receptor by the short acting anaesthetic ketamine can block this process and reduce central hypersensitisation.

Figure 7 Molecular mechanisms of central sensitisation at the dorsal horn. Central sensitisation of dorsal horn neurons by action of neurotransmitters like SP and BDNF to alter the phosphorylation of receptors by PKA and PKC. The result is the lowering of the threshold of activation by glutamate release. BDNF, brain derived neurotrophic factor; PKA, protein kinase A; PKC, protein kinase C; SP, substance P.

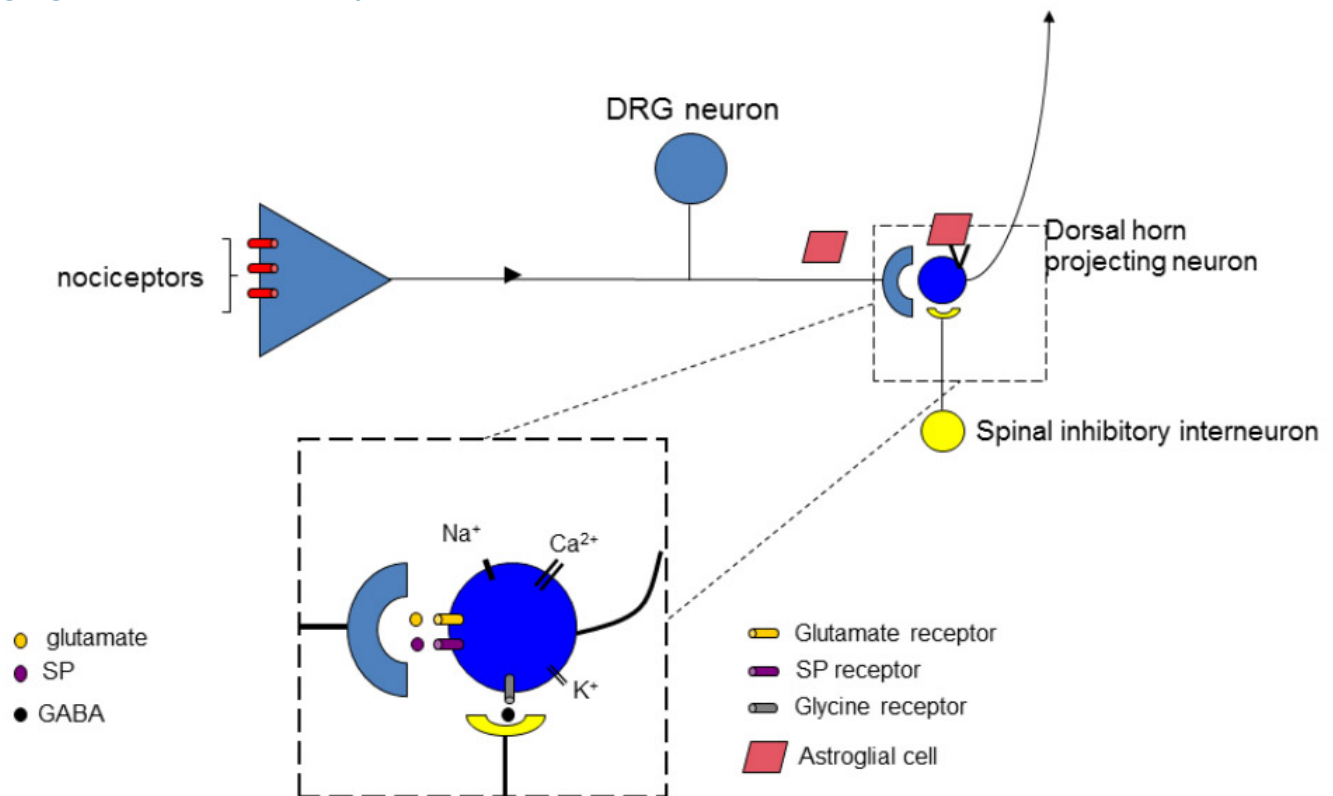

After the early changes in receptor thresholds, subsequent modifications to central neurons occur through transcription of new proteins or increased expression of existing proteins. For example, central neuronal expression of COX-2, induced by $\text{TNF}\alpha$ and $\text{IL-1}\beta$, results in increased PGE2 production locally (figure 6).

6.2.3 Neuronal connections and supporting cells

Other mechanisms that play a part in neuronal plasticity in pain include the loss of neuronal inhibition, the rearrangement of synaptic contacts, and interactions between microglial cells and neurons. During loss of inhibition, inhibitory interneurons in the spine may either become less active or even undergo cell death (figure 8). In animal studies, hyperalgesia from inflammation and neuropathic pain can be improved by GABA

mimetics such as diazepam (Paul 2013). Synaptic rearrangements have been shown to take place following nerve injury. In experimental models, sprouting of new connections from injured A δ fibres have been demonstrated to generate new anatomical projections (Shortland and Woolf, 1993). These phenomena are thought to be influenced by neurotrophic factors such as nerve growth factor (NGF) and glial cell-derived neurotrophic factor (GDNF). Most recently, the interactions between neurons and cells of its supporting matrix, the microglia, have been intensively studied. Instead of a passive supportive role, glial cells are now known to release cytokines including IL-1 β , transforming growth factor β (TGF β), IL-6, and IL-10 in response to inflammatory signals. Indeed pain responses can be substantially reduced in most animal models by interfering with this inflammatory process (Chang 2016).

Figure 8 Dorsal horn neuronal network. Interactions between afferent neurons, dorsal horn cells and inhibitory neurons modulate dorsal horn transmission to the central nervous system. DRG, dorsal root ganglion; GABA, α -aminobutyric acid; SP, substance P.

7 Evaluation of pain

7.1 Pain assessment

As pain is first and foremost a subjective sensation, its assessment relies on the patient's experience. Pain evaluation is a common ingredient in the disease assessment tools used in rheumatology (for example, subscales in the Western Ontario and McMaster Universities Arthritis Index (WOMAC) for osteoarthritis, the Disease Activity Score (DAS) for rheumatoid arthritis, and the Bath Ankylosing Spondylitis Disease Activity Index (BASDAI) score for ankylosing spondylitis). Most of these scores measure pain in a graduated manner,

using a device such as a 10 cm Visual Analogue Scale (VAS), the Numerical Rating Scale (NRS) or the Verbal Rating Scale (VRS), and integrate the results with other measures of disease activity to provide an overall score. However, this type of assessment is based on the assumption that pain is a uni-dimensional experience. That is clearly an oversimplification towards the patient's own perspective. A more comprehensive pain assessment scale that evaluates a number of dimensions of pain qualitatively has been developed by Melzack and is widely used in clinical studies. The McGill Pain Questionnaire (MPQ) was developed to assess the affective and sensory experiences of the patient and has been validated in different languages as well (Melzack and Katz, 2006). This instrument has further given rise to an abbreviated version, the Short Form McGill Pain Questionnaire, that has good correlation with the MPQ itself (Dudgeon et al, 1993). However, mostly such detailed pain assessments as the short McGill have been used for research purposes depending on the resources available. The most important aspect of the clinical assessment is listening to the patient and providing time for them to tell their story. Most patients with chronic pain will have a history of psychological distress and often childhood or adolescent abuse. Trust and calm listening are required for the patient to feel listened to. This in itself may be the first time this has occurred and may have a therapeutic effect. The second aim is to establish the spatial and temporal characteristics of the pain or pains. Many patients will have more than one types of pain. Then try to establish the main driver of the chronic pain. In other words is it mainly nociceptive, neuropathic or psychologically maintained. The latter is mainly a matter of clinical judgement and needs to be confirmed by a thorough clinical examination. Neuropathic pain is relatively easy to identify as it will be accompanied by pain in the distribution of neurological deficit and is often associated with allodynia. The only other situation where allodynia may occur is the whole body allodynia (to light pressure and sometimes touch and brush) associated with fibromyalgia. Often regional pains are not associated with any obvious pathology. If there is no other evidence of arthritis these may develop over time into more widespread pains. However, at the time of consultation they may be difficult to characterize other than with a label of chronic regional pain. In these patients it is important to assess psychological co-morbidities and refer for cognitive therapy if appropriate. Antidepressants are not appropriate for mild to moderate depression as a first line to therapy. The presence of obvious tissue damage-such as arthritis is usually clinically evident in the small to medium sized joints and x-rays are rarely helpful (particularly in osteoarthritis) if there is no evidence of arthritis clinically. Widespread pain either with or without widespread tenderness can be provisionally diagnosed as fibromyalgia. However, it is worth excluding thyroid, calcium and inflammatory muscle disorders (thyroid function, calcium, alkaline phosphatase and creatine phosphokinase). Vitamin D is always worth checking as patients with fibromyalgia are frequently vitamin D deficient although the pain rarely resolves with Vitamin D therapy.

By the end of the clinical assessment it should be possible to make a clinical assessment of the most likely drivers of the chronic pain. This is a helpful construct for the patient but should be reassessed if the symptoms change.

Explanation of the patient's symptoms is probably the most important part of the consultation. Any associated pathologies should be explained in simple and jargon-free terms. In the absence of any physical cause of chronic pain the author finds it useful to explain chronic regional and widespread pain in the following way; 'Pain is sometimes associated with physical damage such as arthritis but more frequently is not associated with physical damage. In chronic widespread pain the brain is under a lot of stress and this is associated with the brain always expecting bad things to happen including pain. This is associated with the widespread pain. Although there is no magic therapeutic wand to get rid of the pain, these fine tuning problems can be helped by talking therapies. Sweaty exercise is also helpful as this activates the natural opiate system in the brain. So these two types of therapy allow you to take more control over how you feel including your pain.'

7.2 Evaluation of the biosocial complexity

Chronic pain engenders affective and psychosocial consequences that may play a role in the pain experience of the patient. Symptoms of depression are commonly reported in patients with chronic pain even though the patient does not have an overt psychiatric disorder—for example, there is a strong correlation between pain intensity and symptoms of anxiety and depression in patients with rheumatoid arthritis (Dickens et al, 2002). Although most chronic pain patients are not clinically depressed, assessments of biopsychosocial factors are appropriate in a clinical comprehensive assessment and may also have a role in management. Many studies of chronic pain conditions (such as low back pain and cervical pain) have shown that a multidimensional assessment and management approach provides better results than a uni-dimensional approach. However, there is not one single instrument that has been found to be applicable to the different chronic pain conditions. In low back pain, Waddell and colleagues have developed an assessment of non-organic factors based on a limited number of clinical signs (Waddell and Burton, 2005), but this is not validated in other conditions of musculoskeletal pain. Many different assessment instruments have been developed and validated, some of them being disease specific and others generic. Examples of the latter include the general health status instrument SF-36 that has been applied in many different clinical conditions (Ware et al, 1980). Another instrument, the Intermed evaluation scale, has proven clinical utility as an assessment tool in chronic rheumatological conditions and may be helpful in selecting patients for more specific treatments (Stiefel et al, 1999; Koch et al, 2001).

Sleep disturbances are often present in chronic pain patients, a typical example being fibromyalgia. The mechanisms are poorly understood, but chronic fatigue due to sleep disturbance probably plays a primary role. Interestingly, patients with chronic low back pain also report significant levels of sleep disturbance (Kelly et al, 2011). It has been suggested that sleep disturbance should be assessed as a distinct item in clinical trials in fibromyalgia.

8 Non-pharmacological Management of Pain

8.1 Neurobiological effects of exercise

Non-pharmacological treatment approaches have shown to decrease pain and improve function by significantly. Exercise treatment regimes are often recommended when managing pain related symptoms and these can vary depending on the pathology and the location of pain. Exercise treatment regimes are often recommended as part of a rehabilitation programme tailored to individual patients and have shown up to a 30% reduction in pain and up to a 20% improvement in function (Turk D et al, 2011). Further studies have revealed neurobiological relationships between exercise and pain. As discussed earlier, chronic pain can be as a result of increased inflammatory cytokines. Inflammatory markers such as TNF- α and IL-6 are also increased acutely after exercise (Cooper et al, 2016). This increase in cytokines from exercise is thought to trigger a robust anti-inflammatory cascade which ultimately results in an increase of anti-inflammatory markers. Overall, long term regular exercise leads to an increase in anti-inflammatory cytokines and a decrease in pro-inflammatory markers. Furthermore, exercise has shown to increase endogenous opioids in brainstem regions important to pain processing. This suggests that exercise may reverse neuropathic pain by upregulating endogenous opioids. Although there is variability of analgesic effects in non-healthy individuals, exercise is still viewed as beneficial in reducing pain in disease and should be considered as one of the first treatment options as it is a relatively safe approach.

8.2 Psychological therapies

Psychological approaches to the management of pain are generally split into two categories: theoretically-based approaches and specific techniques (Turk D et al, 2011). The commonest theoretical approaches include operant conditioning, mindfulness-based therapy and cognitive-behavioural therapy. These types of approaches focus on patient coping, adaptation, self-management and reduction of disability associated with symptoms. This is achieved by cognitive therapy, relaxation and hypnosis to enable patients to take control of their symptoms and develop an active and resourceful attitude towards their pain. By replacing feelings of hopelessness with control, patients can avoid catastrophizing and feeling demoralised towards their pain. Meta-analyses and systematic reviews show that psychological therapies result in modest benefits in improvement of pain and physical and emotional functioning. However, the most amount of benefit is seen when they are included as part of a rehabilitation programme. Rehabilitation programmes do not follow a specific format, but use an integrated approach led by a multidisciplinary team. Components of a rehabilitation programme include physical rehabilitation, exercise therapy, behavioural treatment, cognitive restructuring via education, vocational rehabilitation and pharmacological approaches. One of the main advantages of non-pharmacological approaches is its relative safety when compared to pharmacological treatments. This is due to the side effects of analgesic drugs. It is important to note that multiple meta-

analyses report that rehabilitation programmes result in reduced healthcare use and a significant reduction in pain by as much as 37% in one analysis (Hoffman et al, 2007). The current evidence suggests that rehabilitation programmes may be as effective as traditional pharmacological therapies and therefore patients with resistant symptoms should be considered for such options.

9 Pharmacology of analgesics

9.1 NSAIDs and COX-2 inhibitors

NSAIDs are the most commonly used agents in the treatment of pain. Their many facets of action are still under investigation decades after the initial discovery by Vane of the ability of aspirin-like drugs to inhibit prostaglandin synthesis (Vane, 1971). This discovery opened the door to the pharmacological study of antipyretic analgesics and the subsequent discovery of the two isoforms of cyclo-oxygenase, COX-1 and COX-2, providing a rational understanding of the pharmacological action of NSAIDs (table 3). As already detailed above, prostaglandins, in particular PGE₂, enhance nociception by acting on peripheral nerve terminals as well as acting centrally. COX inhibitors are used routinely in clinical practice for their antipyretic as well as analgesic effects. Both enzymes (COX-1 and COX-2) metabolise arachidonic acid to the two prostaglandin precursors PGG₂ and PGH₂. Through the action of PGE₂ synthases—enzymes that are bound to microsomal membranes and are closely coupled to the COX enzymes—the precursors are converted to PGE₂ (figure 9).

Table 3 Pharmacological properties of common non-steroidal anti-inflammatory drugs

Class	Name	T _{1/2}	pKa	Protein binding (%)	Maximum daily dose in adults
Low potency/fast elimination	Aspirin	20 min	3.5	>80	6 g
	Salicylic acid	2.5–7 h	2.9	>90	6 g
	Ibuprofen	2–4 h	4.4	99	3.2 g
	Mefenamic acid	1–2 h	4.2	>90	1.25 g
High potency/fast elimination	Ketoprofen	0.5–2 h	4.2	99	300 mg
	Diclofenac	1–2 h	4	99	200 mg
	Indomethacin	2.6–11.2 h*	4.5	99	200 mg
Intermediate potency/intermediate elimination	Diflunisal	8–12 h	3.8	98	1 g
	Naproxen	13–15 h	4.1	99	2 g
High potency/slow elimination	Meloxicam	18–36 h	4.9	>99	15 mg
	Piroxicam	14–160 h	5.1	>99	40 mg

*Presence of enterohepatic circulation.

Figure 9 Prostaglandin (PG) synthesis from arachidonic acid. Summary of the role of cyclo-oxygenases in PGE₂ production and the differential expression of COX-2 during inflammation. COX, cyclo-oxygenase. (Reproduced with permission from Zeilhofer and Brune, Trends Pharmacol Sci 2006;27:467–74*.)

The understanding of the physiopathological actions of prostaglandins and their inhibitors in nociception has been facilitated by knock-out of the different COXs and the receptors (reviewed in Brune and Zeilhofer, 2006; Zeilhofer and Brune, 2006*). COX-1 knockout mice did not show a nociceptive phenotype whereas COX-2 deficient mice showed impaired nociceptive reflexes. Mice deficient in the prostaglandin receptors EP₁, EP₂, EP₃, and EP₄ showed reduced nociception in a number of experimental settings. EP₂ deficient mice also showed no hyperalgesia after intrathecal injection of PGE₂, suggesting that this receptor has a central role as well.

9.2 COX-2 inhibitors

Aspirin (acetylsalicylic acid) is the prototypic COX inhibitor and serves as a useful paradigm for our understanding of the mechanisms of action of this class of drug, though it only has a minor place in the treatment of pain in clinical settings. Its molecular mechanism of action is the irreversible inactivation of the COX enzyme's active site by acetylation. However, aspirin has a higher affinity for COX-1 than COX-2. Moreover, as de novo synthesis of COX-1 does not occur in platelets, the prominent antiplatelet effects and gastrointestinal (GI) toxicity in comparison with other non-steroidal agents is explained. The differences in tissue distribution of the two forms of COXs as well as their different transcriptional regulation supported the notion that, in inflammatory states, COX-2 mediated production of PGE₂ accounts for the known clinical effect

on nociception as well as cellular effects on, for example osteoclasts, T lymphocytes as well as dendritic cells that can play a part in the inflammatory site (Anderson et al, 1996). The first generation of NSAIDs inhibited to a varying extent both COX-2 and COX-1, and were termed non-selective COX inhibitors.

Based on the roles of COX-2 in inflammation, pharmacological inhibitors that are selective for COX-2 inhibitors (COXIBs) are expected to show a somewhat better therapeutic profile. However, one must not forget that COX-2 is also produced constitutively in the kidney, brain, and blood vessel wall. Mice that are deficient in COX-2 demonstrated renal impairment and developed atherosclerosis. Development of selective COX-2 inhibitors as therapeutic agents was greeted with initial enthusiasm, based on the proposition that these drugs should be devoid of relevant GI toxicity, but show efficacy in different painful conditions. Clinical studies confirmed there was a lower incidence of GI side effects with these drugs; however, the incidence of cardiovascular side effects (stroke, myocardial infarction, thrombosis) was significantly increased in some studies where the control group received the conventional non-selective NSAID naproxen. This difference is not seen in comparison with diclofenac or ibuprofen. Different mechanisms have been proposed to account for these observations: the inhibition of prostacyclin production by COXIBs, hypertension, fluid retention, and effects on endothelial function. As a consequence, several drugs were withdrawn and the development of others suspended. As of the time of writing, only celecoxib and etoricoxib are still marketed.

Indeed, the cardiovascular side effects observed in the COXIB clinical studies have raised the question of whether conventional NSAIDs can also pose a cardiovascular risk. Several long term studies investigating the cardiovascular risk of selective and non-selective COX inhibitors demonstrated that all compounds, even acetaminophen, were associated with an increased risk of cardiac infarction and other cardiovascular damage.

The cardiovascular side effects are probably linked to the inhibition of endothelial production of prostacyclin (Grosser et al, 2006*). Naproxen appears to differ from all other selective and non-selective COX inhibitors as this compound is not associated with an increased incidence of myocardial infarction (at high doses) in a meta-analysis of published randomised trials (Kearney et al, 2006*). Pharmacologically, naproxen can significantly inhibit COX-1 activity in platelets in the short term, down to levels observed on treatment with low dose aspirin, and interfere with platelet aggregation (Capone et al, 2007). However, naproxen is not devoid of upper GI tract toxicity (Rahme and Nedjar, 2007) and it has also been reported to cause significant lower GI toxicity, even when given together with a proton pump inhibitor (Goldstein et al, 2005). These findings have clinical and therapeutic implications, as recent guidelines by the European Medicines Agency (EMA) have stated that traditional non-selective NSAIDs are contraindicated in patients who have had two or more GI bleeds, and should be used with caution in patients with known cardiovascular risks. As already indicated previously, COXIBs are contraindicated in patients with known cardiovascular risks, though they may be used in patients who have GI bleeding risk. The unresolved question is how to treat a patient who presents both cardiovascular and GI bleeding risks. Expert opinion suggests that it may be better in this situation to prescribe a combination

of a traditional non-selective NSAID, a proton pump inhibitor, and low dose aspirin. This option, however, is questionable as a recent large population study indicates that this combination may blunt the cardioprotective effect of aspirin (Charlot et al, 2011).

The side effect profile of NSAIDs is also similar, the most important being GI, renal, cardiovascular, and central nervous system side effects. Table 4 provides a summary of the side effects that are encountered with NSAID therapy and the putative mechanisms. COXIBs were not detailed specifically, but they share some of the properties detailed (eg, effects on renal function). COXIBs may be safer in terms of bleeding risk in the setting of concomitant anticoagulation and may have a safety advantage in patients who have known aspirin-induced asthma. As the selectivity of inhibition of COX-1/COX-2 varies between agents, some of these drugs may also have an antiplatelet effect, though nowhere near that obtained with aspirin. It is notable that most NSAIDs are acidic molecules with similar degrees of plasma protein binding. Compounds do, however, differ in two properties—potency and pharmacokinetics—that can alter their effectiveness in a given patient or clinical situation.

9.3 Paracetamol

Paracetamol (acetaminophen) is an aniline derivative and is a non-acidic antipyretic analgesic. It is a weak inhibitor of COX-2 in vivo and ex vivo, which explains its (weak) antipyretic effect (Graham and Scott, 2005; Hinz et al, 2008). As an analgesic, it is less potent than NSAIDs and has to be given at relatively large doses with relative safety. Its main toxicity is on the liver. Liver toxicity is due to its benzoquinone metabolite, mediated by the hepatic enzyme CYP450, which can bind covalently to DNA and structural proteins in hepatocytes to produce necrosis. It has recently become obvious that paracetamol not only shares all side effects of NSAIDs, but in addition induces liver damage at therapeutic doses (Brune et al, 2009; Brune and Hinz, 2011). Recent metaanalysis of trials in chronic pain has cast some doubt about the long-term efficacy of paracetamol (Roberts et al, 2015) when compared to placebo treatment. This raises issues about its place in chronic pain management. One of the problems is that patients with arthritic pain may have a combination of acute recurrent pain and chronic unremitting pain. It is not always clear from drug trials which pains are being targeted. Paracetamol or combinations with low dose opiates such as codeine have been a traditional first line of treatment where patients can make their own choices of when they take them. There is currently no obvious alternative oral therapy for this first step in self-managed analgesia. We probably need to understand more about patient's needs and motivations at this initial level of analgesia, but one possibility is exploring the possibility of prescribing placebo by mutual consent, as we know that placebo has potent and long-term benefits with relatively few side-effects (Colloca and Benedetti, 2005)

Table 4 Side effects of NSAIDs and COXIBs

Organ system	Proposed mechanism	Comments
Gastrointestinal <ul style="list-style-type: none"> • Gastric irritation • Upper GI bleeding • Lower GI bleeding 	Inhibition of gastroprotective effects of COX-1 activity in the upper GI tract Local effect of slow release drugs and enterohepatic circulation influences injury to the small intestine	Coexisting factors influence the risk of GI bleeding during NSAID therapy. Some of these factors are (1) previous bleeding, (2) age, (3) glucocorticoid therapy (Langman <i>et al</i> , 1994) and use of SSRIs Lower GI ulceration and bleeding are often silent but incidence may be greater than reported (Allison <i>et al</i> , 1992)
Renal <ul style="list-style-type: none"> • Oedema • Hypertension • Renal failure 	Renal vasoconstriction in subjects with pre-existing renal disease	The risk of acute renal failure is particularly high in the first 30 days following initiation of therapy (Schneider <i>et al</i> , 2006)
CNS <ul style="list-style-type: none"> • Depression • Cognitive dysfunction • Aseptic meningitis 		Cognitive dysfunction is frequently reported, but aseptic meningitis is a rare complication
Cardiovascular <ul style="list-style-type: none"> • Myocardial infarction • Heart failure 	COX inhibition can interfere with platelet function as well as endothelial vasodilator mechanisms (prostacyclin, NO production). In addition, renal effects of COX inhibition can lead to hypertension, a risk factor for atherosclerosis	There is considerable controversy about the risk of conventional NSAIDs. Certain COX-2 inhibitors, such as rofecoxib and valdecoxib, have been withdrawn from sale (McGettigan and Henry, 2006)
Haematological <ul style="list-style-type: none"> • Haemolytic anaemias • Bleeding 	Inhibition of COX-1 in platelets leads to reduced production of thromboxane A ₂ and platelet aggregation	NSAIDs can interact with anticoagulant therapy to exacerbate bleeding Neutropenia is infrequent but an association with NSAID therapy has been demonstrated (Strom <i>et al</i> , 1993)
Dermatological		Toxic epidermal necrolysis (Stevens-Johnson's syndrome) is rare. Risk appears greater with the oxicam class of NSAIDs (Mockenhaupt <i>et al</i> , 2003)
Hepatic <ul style="list-style-type: none"> • Liver enzyme alterations • Hepatitis • Liver failure 		Liver enzyme elevations are commonly encountered with NSAID therapy. Individual drugs and the clinical context may play a role (Furst and Anderson, 1993). Liver failure is infrequent (3.7/100,000 users) (Garcia Rodriguez <i>et al</i> , 1994), but high with paracetamol
Others <ul style="list-style-type: none"> • Foetal effects 		COX inhibition in pregnancy may result in the premature closure of the ductus arteriosus and bleeds

CNS, central nervous system; COX, cyclo-oxygenase; COXIBs, COX-2 inhibitors; GI, gastrointestinal; NO, nitric oxide; NSAIDs, non-steroidal anti-inflammatory drugs; SSRIs, selective serotonin reuptake inhibitors.

Some superficial rheumatological conditions are amenable to local treatments applied to the joint and to periarticular tissues. The use of topical formulations of NSAIDs has grown over the last two decades, as topical formulations (in the doses used) do not have the toxicity profile of systemic administration. A small amount of drug enters the plasma after topical application, but the concentrations found in the subcutaneous tissues and joint fluid are within the therapeutic windows of the drugs studied. However, the joint fluid concentration after topical application remains significantly lower than that found after oral administration (Erdogan et al, 2006; Rainsford et al, 2008).

Currently, topical therapy can be applied directly to the skin, whereby the drug diffuses continuously through the skin to the symptomatic area. Randomised controlled trials in patients with different forms of osteoarthritis and soft tissue rheumatic disorders have shown that there is a small analgesic effect with these preparations, but the effect is only significant during the first 2 weeks. The side effect profile is similar to that found in placebo treated subjects, but shows more skin irritation. Ketoprofen preparations are associated with increased phototoxicity. In one meta-analysis, the number needed to treat to obtain a positive effect was calculated to be 4.6 (Lin et al, 2004*; Mason et al, 2004). Topical treatment has been recommended as a therapeutic option in the management of knee osteoarthritis (Jordan et al, 2003), but convincing data are from smaller joints—for example, in patients with osteoarthritis of the finger.

9.4 Opioids

The pain relieving effects of opium, derived from the poppy *Papaver somniferum*, were recognised by ancient healers. Our current therapeutic opioids are all derivatives of morphine. Derivates of opium are called opiates, and synthetic analogues are called opioids. Opioid drugs act through the opioid receptors whose physiological actions have already been described. The first opioid receptor to be cloned was the mouse δ receptor (DOP-R) in 1992 and this led to the identification of the μ (MOP-R) and κ (KOP-R) receptors. Cloning of the opioid receptors has allowed detailed studies of the different ligands (endogenous and exogenous) with the different receptors and their effects in vivo.

The analgesic and adverse effects of opioids are mainly mediated by their binding to the MOP-R, though there are some data to suggest that agonists for DOP-R also exert an analgesic effect. Experiments with knockout mice showed that MOR mediates all morphine's activities (including its side effects), whereas the KOR knockout mice had little effect on nociception, but showed stress-induced behavioural changes.

In clinical use, opioids are the most powerful analgesics available and their use is of immense therapeutic value. However, they are also associated with known pharmacological side effects. In rheumatoid arthritis, osteoarthritis and common rheumatological conditions, strong opiates are not a first-line choice. Combination effect opiates such as tramadol (combined opioid and 5HT effects) and tapentadol (combined opioid and noradrenergic effects) probably occupy an intermediate place although tapentadol is conventionally regarded

as a strong opioid. Physicians prescribing opioids should be aware of the common side effects that include dizziness which may lead to falls and fractures. Dose-dependent side effects include respiratory depression, euphoria, feeding, reduced GI transit, effects on anxiety, and endocrine and immune effects.

Prolonged use can, however, produce ‘tolerance’, a physiological phenomenon resulting in a diminished analgesic effect or ‘dependence’—the necessity for continued drug intake in order to prevent the symptoms of opioid withdrawal.

The main opioids in routine clinical use are summarised in table 5; their ‘analgesic equivalence’ is presented in table 6. Many opioids have multiple forms of administration, ranging from oral to topical, and detailed knowledge of the features of each route of administration, as well as the drug’s suitability, is required for optimising treatment. The main pharmacological aspects of some of these drugs are detailed in the section below.

Table 5 Functional classification of opioids

Full agonists	Morphine Fentanyl Hydromorphone Codeine (via its metabolite morphine) Methadone Tramadol Pethidine
Partial agonists	Buprenorphine Pentazocine Butorphanol
Agonists–antagonists	Nalbuphine Nalorphine
Full antagonists	Naloxone Naltrexone

Morphine, hydromorphone and codeine are opiates. The others are opioids. For explanation, see text.

Table 6 Equianalgesic doses of opioids

	Dose with analgesic activity equivalent to 10 mg morphine
Pethidine	100
Codeine	90
Dihydrocodeine	60
Tramadol	50
Oxycodone	7.5
Hydromorphone	2
Methadone	1
Buprenorphine	0.3

9.5 Strong opioids

Morphine remains the standard to which all other opioids are compared in terms of clinical efficacy and tolerance. It is most often prescribed orally or by subcutaneous injection, but can also be injected directly into sites such as the epidural space and the spine. Following absorption, morphine is metabolised to its glucuronide derivatives.

Morphine-6-glucuronide has an analgesic effect, whereas morphine-3-glucuronide accounts for the adverse effects. The balance between these two major metabolites can be altered by conditions such as renal failure. Hence morphine should be used with care in that situation.

Other strong opioids include oxycodone, hydromorphone, and buprenorphine. Oxycodone is a semi-synthetic derivative that has become the most widely prescribed opioid worldwide, marketed as a single substance or in combination with paracetamol. It has a higher bioavailability after absorption and is metabolised by liver cytochrome P450 to oxymorphone (Kalso, 2005). Buprenorphine is another semi-synthetic derivative that has partial agonist activity for the MOR and antagonist activity for the KOR.

Currently, the drug is given by sublingual or transdermal administration to overcome high first-pass metabolism and has a half-life of around 37 h. As it is mainly eliminated by hepatic metabolism, there is less risk of toxicity when it is used in patients with renal impairment. Because of its partial agonist activity it is much less likely to cause respiratory depression and can also be started at low doses as a patch.

It must be emphasised that all strong opioids possess similar pharmacologic side effects to those of morphine (nausea, vomiting, respiratory depression, etc), so the same caution applies whenever they are prescribed, though there may be slight differences in effects such as itching (less with oxycodone) and respiratory depression.

9.6 Weak opioids

Codeine is an alkaloid of opium that is metabolised in the liver to glucuronide derivatives of morphine, and to morphine itself (2–10% of the codeine dose), which accounts for its analgesic effects. This latter step is mediated by CYP2D6, an enzyme that is lacking in 9% of the Caucasian population, which accounts for the lack of analgesic effect in some patients. When given with other medications that inhibit CYP2D6 (such as citalopram and fluoxetine), the effectiveness of codeine may be impaired.

Tramadol is not an opioid in the classical sense, as it acts on the MOR as well as on serotonergic and noradrenergic neurotransmission. It is used widely as a mild analgesic and has the advantage that, at equianalgesic doses, it results in less constipation than morphine and causes less dependence and respiratory

depression. However, nausea and vomiting are common side effects and tramadol may cause postural hypotension due to its 5HT effects. The new drug tapentadol is very similar in its pharmacological profile.

9.7 Neuropathic pain and mode of action of anticonvulsant analgesics

Damage to peripheral nerves frequently results in spontaneous pain and/or enhanced nociception and is a frequent problem confronting physicians. Examples are persistent nerve root pain after herpes zoster neuropathy, lumbar disc surgery, phantom limb pain, and painful peripheral neuropathies in the context of systemic diseases. In these examples, there is no evidence of an ongoing nociceptive stimulus, and the persistence of pain could be explained by prior nerve damage leading to long term remodelling of nociceptive transmitters and neuronal circuits (see section 6.1 on plasticity). Clinical management of these conditions is often complex, requiring multiple pharmacological interventions and sometimes even invasive procedures, such as spinal cord or brain stimulation.

No single pharmacological class has been found to be universally effective, but among the pharmacologic agents, anticonvulsant drugs, tricyclic antidepressants and opiates have a place. Indeed, since the discovery of phenytoin, physicians have treated pain syndromes empirically with available anticonvulsants. Examples include carbamazepine and more recently gabapentin and pregabalin. Randomised controlled trials, however, are still scarce and inconclusive.

9.8 Mode of action of anticonvulsant analgesics

Phenytoin acts by blocking voltage-gated sodium channels, inhibiting the repetitive firing of injured nerves and suppressing spontaneous discharges, while carbamazepine acts on voltage-gated sodium channels in a voltage- and frequency-dependent manner. Gabapentin is a structural analogue of GABA and binds to the $\alpha 2\delta$ subunit of the voltage dependent Ca^{2+} channel. It inhibits high-threshold calcium currents in cultured neurons and inhibits the release of excitatory amino acids, such as glutamate, through its actions on the calcium channel (Fink et al, 2000). Finally, gabapentin also interacts with the NMDA receptor. The pharmacological properties of the commonly used agents are summarised in table 7. In clinical use, both phenytoin and carbamazepine have narrow therapeutic windows, and side effects such as somnolence and dizziness are common. Gabapentin has similar side effects, but in clinical practice does not seem to be as disabling as the other agents. Pregabalin is an analogue of gabapentin and its pharmacological actions are similar.

Table 7 Properties of commonly used anticonvulsants in neuropathic pain

	t_{1/2} (h)	Therapeutic dose (in neuropathic pain), mg/day	Clinical evidence for efficacy in randomised controlled trials
Phenytoin	6–24	<300	Diabetic neuropathy Mixed neuropathy Fabry's disease
Carbamazepine	25–65	100–1200	Diabetic neuropathy Trigeminal neuralgia Post-herpetic neuralgia
Gabapentin	5–7	900–2400	Phantom limb pain Mixed neuropathy Diabetic neuropathy Spinal cord injury pain Guillain-Barré syndrome
Pregabalin	6	100–300	Diabetic neuropathy Post-herpetic neuralgia

9.9 Role of antidepressants in pain management

Because chronic pain patients often manifest depressive symptoms, empirical therapy with antidepressants was introduced. Their initial positive effects led to further randomised clinical trials that confirmed an analgesic effect. The principal question in the use of antidepressants for treatment of pain is whether the analgesic effect is linked to the antidepressive action of these drugs. Because the analgesic effects come on prior to changes in mood they have been traditionally considered to have analgesic effects in their own right.

As the pharmacological spectrum of antidepressive drugs increases, so does our understanding of their mechanisms of action in pain. Not all antidepressants show the same efficacy in pain management, and from meta-analyses of published data it is now recognised that mixed inhibitors of serotonergic and noradrenergic transmission are more effective than agents that work on single pathways.

The proposed mechanisms of action of antidepressants include the activation of serotonergic and adrenergic pain inhibitory circuits that descend from the midbrain and brainstem to the dorsal horn, but other pharmacological actions (on acetylcholinergic transmission, on the NMDA receptor as well as on ion channels) have also been described (reviewed in Watson *et al*, 2006).

Currently, three main classes of antidepressants are in use: the tricyclic antidepressants (TCAs), the selective serotonin-reuptake inhibitors (SSRIs), and the combined serotonin-noradrenaline reuptake inhibitors (SNRIs). A review of the use of these agents in a randomised controlled trial setting in different pain states showed that the most effective class for pain are the TCAs in a wide variety of settings (neuropathic pain, arthritis pain,

headaches). This class of drugs include amitriptyline, nortriptyline, trimipramine, and ritanserin. Side effects common to this class include anticholinergic effects, sedation, and orthostatic hypotension, though some agents (such as amitriptyline and trimipramine) are more sedative than others (Watson *et al*, 2006; Wise *et al*, 2007*). In general, SNRIs have a better side effect profile, but their effects on pain may not be as potent as TCAs. SSRIs appear to be the least effective in pain indications, but would treat depression as a co-existing pathology.

10 Conclusion

The priority when assessing patients with chronic pain is to define and assess any underlying disease process. However, assessment of the likely drivers of the chronic pain can go in parallel to this process. With the awareness that in most cases there will not be a clear relationship between any defined disease process and the patients pain symptoms. The choice of analgesics and non-drug therapies for chronic pain is therefore not based less on the disease process, but more on the presumed physiological drivers of pain in an individual patient (i.e. is it mainly nociceptive, neuropathic or psychologically maintained). This is mostly based on clinical assessment and judgement rather on objective tests and where there is uncertainty, it is fine to share this with the patients. It is also vital that the underlying disease causing pain is assessed and treated in the most effective way possible, and in the case of rheumatic diseases, treatment targeting the inflammatory and immune processes can alleviate pain significantly. However, in clinical day-to-day settings, it is important that patients made aware of both the physical and psychological components that may affect their pain and their response to this. In practice, most patients will start with simple and safer analgesics with or without some advice about exercise. There is relatively little evidence-based guidance as to what types of therapies should be embarked on in which order. This will in many cases be determined by what resources the clinician has access to. However, much will be determined by the patient's biases about therapy. Greater engagement is likely if the patient and clinician are enthusiastic about the type of treatment offered. In practice there is no evidence for one particular type of therapy (drug, exercise/physiotherapy or cognitive therapy) being uniquely effective in any type of chronic pain. In back pain there is evidence for a stepped approach being effective. In authors experience it is generally better to offer a choice of all of these types of therapy and to allow the patients choice to influence combinations of therapy that they engage with. Although resources are an issue in some health communities, especially access to CBT, a great problem is the patients continued engagement with effective therapies over time, which relies on a good therapeutic relationship between the health care professional and the patient. This requires deliberate allocation of adequate time in whatever clinical setting the patient is being advised in.

In acute painful states, a step-up approach with a combination of analgesic agents is often applied. Initial therapy is usually with an NSAID. Many guidelines suggest paracetamol alone or in combination with an NSAID or opioid. Recent evidence, however, suggests that these combinations may have disadvantages as there is not

only no gain in effectiveness, but even an increase of unwanted drug effects (Doherty *et al*, 2011*). A combination with a weak opioid may be tried. There is no evidence that combining two different NSAIDs augments the effect and indeed it may increase the incidence of adverse effects. If pain relief is insufficient with weak or intermediate opioids such as codeine or tramadol, consideration should be given to the use of strong opioids such as morphine and its derivatives, though the evidence base for their efficacy is mainly based on short term studies. In the past 10 years, morphine-like drugs have been more widely used and this has raised questions about the risk of tolerance, addiction, and withdrawal symptoms, particularly in chronic therapy (Ballantyne and Mao, 2003). The additional use of antidepressants and anticonvulsant classes of drugs needs careful clinical assessment and the patient may benefit from a multidisciplinary team assessment. The weight gain and other side-effects associated with these should be discussed with the patient.

The optimum long term management of chronic pain should aim to rely as much as possible on self-management. The role of the health care professional is to facilitate this process and to empower the patient along this path in a non-judgemental way. This may comprise regular exercise, using the principles learned from CBT and other adjunctive activities such as meditation, hypnosis, yoga and tai-chi. Any activities which facilitate reduced social isolation such as art-therapy and group recreation are likely to be helpful. Likewise the use of therapies where the evidence for being better than placebo is questionable (e.g. acupuncture, TENS) should be discussed, based on the patient's needs, costs and potential to do harm. As placebo represents the brain taking control of symptom expression which should be encouraged if it is neither costly or harmful.

The optimal drug therapies are with relatively safe analgesics that the patient can make their own decisions about on a daily basis. Drug holidays are likely to be useful in avoiding long-term side-effects such as dependence. The patient should be as well educated about both their condition and the effects of different therapies as possible to the point where they confident in making decisions about their own pain management.

One frequently posed question of who should provide this service for patients with musculoskeletal and neuropathic pain ? There is no definitive answer to this question, but in the authors view this should be a collective health-care community activity which, however, does require some leadership either in primary or secondary care. Where there is not diagnostic uncertainty then all the appropriate management can be provided in primary care with opportunities for review in secondary care where necessary. Where there is diagnostic uncertainty it may be appropriate that this should be provided in secondary care. In practice a partnership between primary and secondary care is often effective as patients with chronic pain represent a significant demand in primary care which is sometimes difficult to meet. The essential issue is that whichever health care professional takes on this primary responsibility, that sufficient mutual trust and confidence is established to facilitate optimal long-term management aimed at eventual self-management. The principles of chronic pain management are sufficiently simple that all health care professionals can engage with this central

aspect of medical care in a co-ordinated way. Delegation to any particular branch of the health-care system is likely to result in that branch being overwhelmed.

Technical advances using smart self-monitoring, more effective and safer analgesics and smart neurotherapeutics such as neuro-feedback are likely to make this task much easier in the future.

SUMMARY POINTS

- **Nociception is the fundamental biological process underlying pain perception and involves activation of neural pathways that ascend from the periphery to the brain.**
- **The information processed within pathways transmitting nociceptive information is not fixed and can be modified at each level of processing.**
- **The perception of pain is a balance of nociceptive inputs from the body and what the brain is expecting. As such cognitive and affective influences have a major influence on how pain is perceived.**
- **There are powerful control mechanisms from higher brain areas such as the prefrontal cortex that occur naturally.**
- **Neuroplasticity of pain transmission is an important mechanism in chronic pain.**
- **Inflammatory mediators, like prostaglandins and cytokines, modify nociception at the level of the nerve and the brain.**
- **Ion channels on neurons play an important role in nociception and are modified by many different classes of analgesics.**
- **The analgesic effect of non-steroidal anti-inflammatory drugs is through inhibition of PGE2 synthesis.**
- **Opioids relieve pain by binding to opioid receptors that alter ion channels and neuronal excitability.**
- **Tricyclic antidepressant drugs have a superior analgesic effect to serotonin-reuptake inhibitors.**
- **Integrated management using drug and non-drug therapies should be aimed at the eventual goal of self-management.**
- **The more empathic you are with your patients the more likely you are to enhance these powerful mechanisms.**
- **There are powerful control mechanisms from higher brain areas such as the prefrontal cortex that can influence the perception of pain that occur naturally that can be enhanced by drug and non-drug therapies.**

Pain: mechanisms and management

Alexander So, Anthony Jones, Nadeem Jamal

A previous version was co-authored by Alexander So, Jiten Patel, Sylvie Revaz, Jean Dudler, Kay Brune, Haiko Sprott, Christian Roux, Silvano Adami, Emmanuel Biver

IN-DEPTH DISCUSSION I

Analgesia and pregnancy

There is currently a wealth of literature on the use of anti-rheumatic drugs and DMARDs during pregnancy. Despite this, there is little information on the treatment of pain during the same period, other than the very specific period of labour.

However, virtually every woman will have some degree of musculoskeletal discomfort during pregnancy; and it is estimated that as many 25% of them will have at least temporarily disabling symptoms of some type. Low back pain is one of the most common complaints of pregnancy. It will affect 50% of all pregnant women, being more common in patients with previous back pain. There are numerous other musculoskeletal conditions that may warrant the prescription of some analgesia, excluding patients suffering from inflammatory diseases. It is important to note that any pharmacotherapy may prove problematic during pregnancy, as we remain concerned about any potential risks for the unborn child. Most of the published data are in the form of case reports and small retrospective studies. Nevertheless, sufficient evidence has been accumulated to be able to recommend a safe drug treatment option in most clinical situations. It is important to have some common knowledge to help our patient to make an informed decision.

Paracetamol

Paracetamol is safe throughout the pregnancy and lactation period. Although it does cross the placental barrier, no teratogenic effects have ever been attributed to paracetamol in therapeutic doses. Paracetamol remains the analgesic of choice throughout all stages of pregnancy. Some studies have suggested pharmacokinetic changes during pregnancy. However, this does not appear to be clinically relevant as paracetamol can be used at the usual dosage in this setting. Similarly, excretion in milk is minimal (<2% of the ingested dose) and represents less than 5% of the infant therapeutic dose. Breastfeeding does not represent any contraindication to its use.

Nonsteroidal Anti-inflammatory Drugs (NSAIDs)

The story is not as straight forward with the NSAIDs as for paracetamol. For a thorough review the reader could refer to a recent article by Ostensen et al (2006). Nevertheless, NSAIDs can be used during most of the pregnancy with relative security and are considered Category B medications by the FDA. Broadly, NSAIDs are contraindicated during the third trimester of pregnancy but considered as acceptable before this time point. In addition, aspirin and naproxen may increase the risk of bleeding during early pregnancy.

NSAIDs are contraindicated from gestational week 32 onwards, and one should be cautious about their use between gestational week 20 and 32 as they can promote premature closure of the ductus arteriosus and subsequent foetal pulmonary hypertension, or induce renal insufficiency and oligohydramnios. They also potentially increase the risk of foetal haemorrhage and postpartum bleeding by inhibiting platelet aggregation. Despite the fact that these adverse effects appear rapidly reversible within 48 hours, it is best to avoid them during this period.

Before week 20, NSAIDs can be prescribed without too many concerns. There is currently no evidence of teratogenicity and several population-based cohort and case-control studies have failed to demonstrate any increased risk of congenital malformations with the use of NSAIDs during the first trimester. However, one should warn the patient of a possible slight increased risk of miscarriage due to the effect of prostaglandin inhibition on implantation and placental circulation, an effect related to some cases of transient infertility related to the use of NSAIDs.

Finally, most NSAIDs are excreted in very small quantities in breast milk. Though they have the potential to displace bilirubin and therefore increase the risk of jaundice and kernicterus, breastfeeding is generally regarded as an acceptable risk in patients on NSAID therapy. Nevertheless, one should choose agents with a good safety profile: such as ibuprofen, mefenamic acid and naproxen. Feeding immediately before a dose may also help to minimize the infant exposure to the drug.

COX-2 inhibitors (coxibs)

Though most animal data showed that COX-1 and COX-2 inhibitors have the same effects during pregnancy, there is presently insufficient data to recommend the use of any coxibs during pregnancy or breastfeeding. Mouse knock-outs for the two different isoforms demonstrated dramatically different effects on bone consolidation, a fact to bear in mind before assuming that prescribing a COX-2 specific inhibitor will be absolutely similar to prescribing a non-specific NSAID for the foetus.

Tramadol

Tramadol is usually regarded as safe during pregnancy in most European countries. However, embryotoxic and foetotoxic effects have been demonstrated in mice, rats and rabbits treated with maternally toxic doses. These effects include decreased foetal weight, skeletal ossification and increased supernumerary ribs and have led certain countries to recommend avoiding this drug during the first trimester. However, no foetal toxicity was observed with doses that were not maternally toxic, and no teratogenic effects were observed at any doses. Similarly, certain countries also advise avoidance of tramadol during the last trimester for fear of potential neonatal respiratory depression. Globally, it appears that tramadol is a generally safe alternative if it is needed during pregnancy. We should probably be more careful during breastfeeding as active metabolites are excreted into human milk in amounts that could expose a nursing infant to potential toxic levels if the mother is on full-dose tramadol. Choosing the lowest effective dose and informing the mother of risk should prove adequate in these situations.

Major opioids

Interestingly, major opioids are probably the analgesic drugs where the most data are available in the context of pregnancy, as methadone has been given since the 1960s in pregnant patients with opiate addiction.

Despite the fact that some neonates may display opiate withdrawal syndromes, outcome measures support the safe use of this type of analgesic medication in pregnancy. Methadone, buprenorphine and slow release morphine have been used with adequate safety information in pregnant opioid-addicted women, and thus appear reasonable alternatives for pregnant women in intractable pain, regardless of substance addiction. It is also important to note that methadone is an efficient medication for pain, including neuropathic pain.

IN-DEPTH DISCUSSION II

Peripheral pain mechanisms in osteoarthritis

Joint pain due to osteoarthritis (OA) is common and with prevalence reaching up to one third of the adult population. Current pharmacological treatments of OA joint pain are often ineffective and side effects of the commonly prescribed drugs may pose a therapeutic challenge, especially when used in an elderly population with multiple comorbidities. There is therefore a need to advance our understanding of the causes and mechanisms that mediate joint pain in OA. In the normal joint, both joint (except for cartilage) and peri-articular structures include many sensory nerve fibres that are able to detect and transduce mechanical and nociceptive stimuli. In the presence of local inflammation, the activation threshold of these afferents is significantly decreased to allow nociception even with low level stimuli (Sprott H, 2008).

Pain and prediction of structural progression in osteoarthritis

There appears to be no real correlation between pain intensity and structural damage in OA as assessed by standard radiology. Up to 40% of individuals with severe radiographic changes are symptom-free (Davies et al, 1992). In addition, there is an inconsistent relationship between the magnitude of radiographic changes and the severity of joint pain and disability (Creamer et al, 1999). It is well documented that changes in knee pain do not correlate with the loss of cartilage, but do moderately correlate with synovitis (Hill et al, 2007; Felson et al, 2007). Moreover, radiographic OA and pain appear to be independent predictors of cartilage loss, as described by Saunders et al 2011 (Saunders et al, 2011). An index of different demographic variables (age, sex, and BMI) seems to be the best predictor for the development of knee and hip OA (Schett et al, 2009). Other attempts such as the index to ring finger (2D:4D) ratio (a longer ring finger than index finger is a risk factor for knee OA), elevated synovial fluid IL-15 (early knee OA), or elevated VCAM-1 levels (severe OA) also illustrate interesting approaches regarding this specific topic (Ferraro et al, 2010; Schett et al, 2009; Scanzello et al, 2009).

Peripheral nociception in osteoarthritis

Local inflammation of the synovial tissue is a feature of the symptomatic OA joint. Synovial fibroblasts have the ability to secrete an array of cytokines, chemokines and growth factors and therefore have the capacity to induce pain in nerves, modulate inflammation and promote matrix degradation (Table 1) (Ritchin, 2000). The result is local hyperalgesia. For that reason, the synovial fibroblast has recently moved into the focus of peripheral pain research. Initially, mechanical stimuli, e.g. movement, cause pain exacerbation (Rackel et al, 2010). This is followed by the development of peripheral sensitization, previously demonstrated in an animal model (Brenn et al, 2007). Silent nociceptors become accessorially activated and amplify these mechanisms (Schaible and Grubb, 1993). Other nociceptive molecules/receptors, such as protons and/or prostaglandins, will then be activated (Wendler and Baewald, 2004), e.g., the intra-articular Prostaglandin E2 level will increase (Table 1). Inflammation and matrix degradation will be enhanced, as shown by Attur et al (Figure 1).

Experimental targets to treat local pain in OA

Currently, there is little information available about local pain mechanisms in synovial tissue. Different pain receptors, such as opioid receptors and the TRPV1 receptor, well described in the CNS (see module 39) are found on synovial fibroblasts and they may play a significant role in peripheral nociception. The discovery of these new molecules has provided novel potential treatment targets in the painful joint. However, a comprehensive understanding of their contributions to pain generation is still lacking. There is, for example, very little data about therapeutic measures via the opioid system when injecting opioids intra-articularly which results in the clear inhibition of both pain and inflammation [reviewed in Janson and Stein, 2003; Gunji et al, 2000; Walker, 2003]. Innovative new targets are expected through other systems, e.g. the TRPV1 or the P2X4 receptor system (Sprott H, 2008; Krause et al, 1995; Engler et al, 2007; Reisch et al, 2005).

Future treatment strategies in osteoarthritis

Future local therapeutic treatment strategies may be based on these new scientific findings, such as intra-articular opioid application (Likar et al, 1997; Takeba et al, 2001; Kalso et al, 2002; Stein et al, 1999; Zeidan et al, 2008), antibody or anti-cytokine approaches (Lane et al, 2010; Chevalier et al, 2009), specific pain receptors (Piepoli et al, 2009), or even by using products of nature like cherry or pomegranate juice (Conolly et al, 2006; Hadipour-Jahromy and Mozaffari-Kermani, 2010). Due to these findings, it is becoming increasingly clear that OA is not simply a degenerative disease but also possibly a disease with systemic inflammatory components (Aigner, 2007).

For this reason, different experimental therapies have been tried and have provided promising results. Etanercept-treated rats showed significantly less mechanical hyperalgesia than saline-treated rats at the injected knee joint, which can be explained by its direct action on neuronal targets rather than an attenuation of the inflammation (Boettger et al, 2008). Other anti-TNF alpha-directed drugs as well as anti-IL-1 or anti-IL-6 approaches may act similarly (Table 2). Cytokines are able to activate NGF and TRPV1. Clinical studies have proved their efficacy and side-effect profile; in previous phase III clinical studies, anti-NGF was found to be very effective in treating OA related pain, but the severity of OA in these patients was accelerating and therefore these studies were stopped (Schaible, 2010). Applying TRPV1 antagonists enhances analgesic activity but also attenuates antagonist-induced hyperthermia (Honore et al, 2009). Bisphosphonates might be able to reduce joint pain and reduce subchondral bone loss in OA (Buckland-Wright and Messent, 2007). The results of autologous chondrocyte or mesenchymal stem cell transplantation as a potential cure are currently being discussed (Minas et al, 2009).

It is becoming increasingly apparent that pain associated with OA is at least partly mediated by central mechanisms as well as peripheral pathology. Preclinical and clinical evidence from experimental sensory testing and functional imaging studies suggest a significant role for excessive nociceptive ascending

transmission resulting in the development and maintenance of central sensitisation (Lluch Girbes et al, 2013). This process has become a target for new pharmacological and non-pharmacological therapies. Randomised controlled trials involving the centrally acting drug duloxetine (an SNRI), have demonstrated analgesic effects in adults with knee osteoarthritis (Abou-Raya et al, 2012; Chappell et al, 2009). Alongside such pharmacological approaches, Cognitive Behavioural Therapy and Neuroscience Education should be considered (Lluch Girbes et al, 2013). It is currently believed that our understanding of the mechanisms of central sensitisation in OA remain in their infancy. However, with the increasing body of evidence supporting central mechanisms in OA it is likely that new central targets will be revealed.

Figure 1: Type II collagen degradation in OA cartilage is augmented by PGE₂. Human OA cartilage was incubated with or without PGE₂ (10uM), with or without the MMP inhibitor Ilomastat (5 ug/ml) for 72 h in serum-free medium. Degradation products of type II collagen were determined in the supernatant using the C1,2C ELISA kit. IL-1 served as positive control. The data represents mean +/- SD (n = 3) performed with three individual patient cartilage explants cultures

Table 1: Effector molecules released by synovial fibroblasts

Signal function	Effector molecules
Angiogenesis	IL-8, TGF- β , PDGF, GM-CSF, G-CSF, FGF, VEGF, EGF
Chemo-attractant	IL-8, IL-16, MCP-1, MIP-1 α
Pro-Inflammatory	IL-1, IL-6, IL-7, IL-8, IL-11, IL-15, LIF, PDGF, MIF, GM-CSF, TRX
Anti-Inflammatory	p55 TNFR, p75 TNFR, IL-10
Matrix degradation	PGE2, collagenase, stromelysin, 92 kD gelatinase, cathepsins B, L, and K
Inhibit matrix degradation	TIMP, TGF- β IL-11
Osteoclastogenesis	RANKL, VEGF
Bone formation	TGF- β , BMP-2

EGF, epidermal growth factor; FGF, fibroblast growth factor; G-CSF, granulocyte colony stimulating factor; GM-CSF, granulocyte-macrophage colony stimulating factor; IL, interleukin; LIF, leukaemia inhibitory factor; MIF, macrophage inhibitory factor; PDGF, platelet derived growth factor; RANKL, receptor activity of nuclear factor κ B ligand; TGF, transforming growth factor; TIMP, tissue inhibitors of metalloproteinases; TNFR, tumour necrosis factor receptor; TRX, thioredoxin; VEGF, vascular endothelial growth factor

(From: Ritchlin C (2000) *Fibroblast biology. Arthritis Res* 2:356–60. Published online 2000 June 23. doi: 10.1186/ar112, 11. With permission.)

Table 2: Selected targeted therapies in OA – open studies on clinicaltrials.gov

(Modified after Berenbaum F (2010) *Targeted therapies in osteoarthritis: a systematic review of the trials on www.clinicaltrials.gov. Best Prac Clin Res* 24:107-19, updated October 28, 2011)

Target	Drug	Phase
COX	Valdecoxib/Naproxen	IV
Serotonin/Norepinephrine	Duloxetine	IV
NGF	Tanezumab	III, terminated
FGF	AS902330	I
iNOS	SD-6010	II/III
Cathepsin K	Balicatib	II
Cathepsin S	JNJ 42160443	II
IL-1	Canakinumab	II
TNF α	Adalimumab	III

The targets suggest that episodes of pain are caused by episodes of joint inflammation.

For routine clinical management, the published EULAR management strategies to treat osteoarthritic hip and knee pain, which include pharmacological as well as non-pharmacological measures, should provide a framework for everyday work (see also recommended further reading).

Rehabilitation aspects of rheumatic diseases

Nina Brodin, Emma Swärdh, Mari Klokkeud

A previous version was coauthored by Mari Klokkeud, Till Uhlig, Cornelia van den Ende

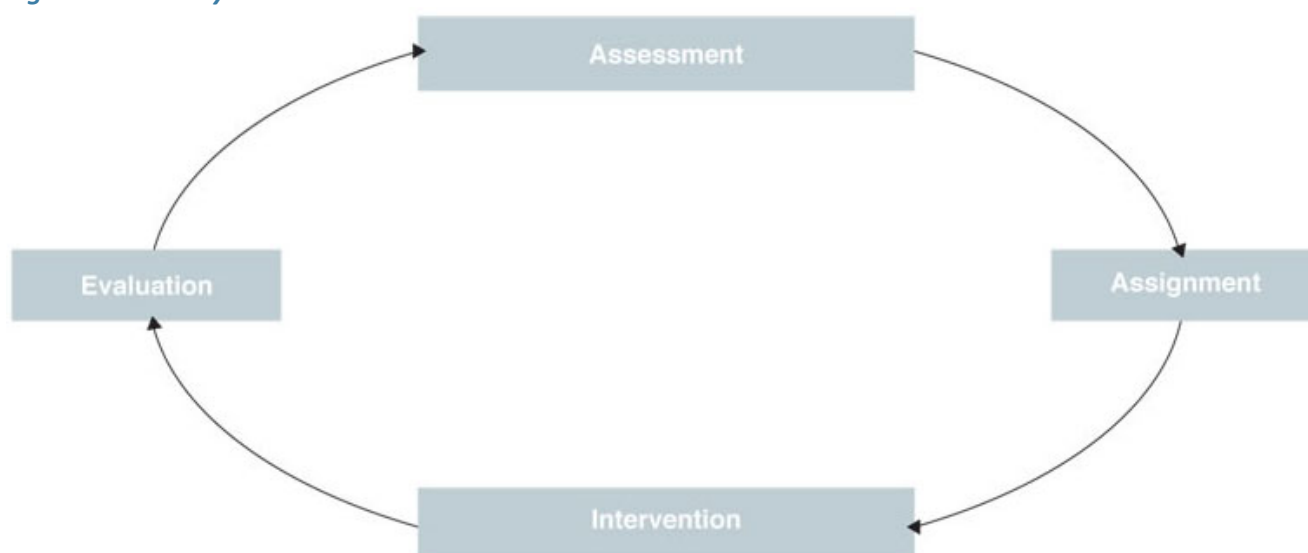

LEARNING OBJECTIVES

- Describe and explain the principles of rehabilitation and use them to devise an individually tailored management plan for patients with rheumatic conditions
- Identify rehabilitation needs and demonstrate appropriate understanding of the possibilities and limitations of rehabilitative treatment modalities for an individual patient
- Properly support patients on self-management skills including lifestyle changes, exercises, the application of activity pacing, and the use of orthoses and adaptive equipment
- Make a substantiated decision on when to refer a patient to a health professional or rehabilitation centre
- Make a valid evaluation of the results of a rehabilitative intervention

This chapter has been developed from the perspective of the rheumatologist and includes issues and tasks he or she needs to know and do with respect to rehabilitation needs of patients with rheumatic conditions.

Rheumatic conditions have a major impact on patients' lives, especially if pharmacological interventions are not available, or effects are small. Symptoms such as pain, stiffness and fatigue may, together with loss of function, causes limitations in daily activities, affect physical activity levels and participation in society. While rheumatologists are focused on controlling the disease process, the derived symptoms and structural damage, they should keep in mind that achieving and maintaining an optimal level of functioning is crucial to the patient's quality of life. This is the aim of the rehabilitation process. This process involves a comprehensive assessment, including collaborative goal setting, the allocation of treatment targets to specific interventions and health professionals, the performance of the interventions and the evaluation of results (the rehab cycle, figure 1) (Stucki and Sangha, 1998). In case of involvement of various health professionals, coordination of rehabilitative care is of the utmost importance.

Figure 1 Rehab-Cycle®.

Rehabilitative interventions include a wide range of modalities, such as physical activity and exercise, self-management support, orthoses, assistive devices, and physical modalities. These interventions can be provided as single treatment modalities, but are often combined in comprehensive rehabilitative management strategies, and are conducted either by the patient themselves, or in collaboration with one or more health professionals. Patient centred care is essential and requires that the patient's preferences, needs and values are considered. Most rehabilitation interventions assume behavioural change, which requires time, knowledge and strategies addressing behaviour change. This can be facilitated by using motivational interviewing, cognitive behavioural therapy (CBT) or theories, for example the Transtheoretical model of behaviour change, Social cognitive theory, Self-determination theory.

Given his or her central role in the management of patients with rheumatic conditions, it is very important that the rheumatologist understands the opportunities and limitations of rehabilitation and rehabilitation treatment modalities. The rheumatologist may advise patients on the optimisation of functioning and to decide when it is time to refer the patient to a health professional, rehabilitation specialist or rehabilitation team.

1 General introduction to rehabilitation

1.1 Definition and goals of rehabilitation

Rehabilitation is by the WHO defined, as a process aimed at enabling people with disabilities to reach and maintain their optimal physical, sensory, intellectual, psychological and social functional levels. Rehabilitation provides disabled people with the tools to attain independence and self-determination” (World Health Organization, 2002). With respect to rheumatic conditions, this applies to management of the consequences of living with the disease, including pain, fatigue, stiffness, deformity, functional disability and physical inactivity. Rehabilitation usually implies the involvement of professionals other than the rheumatologist alone. The professionals most commonly involved in rheumatology rehabilitation are often referred to as the ‘multidisciplinary team’. The rheumatology multidisciplinary team usually comprises, in addition to the rheumatologist, professionals such as nurse specialists, physical therapists, occupational therapists, social workers, dieticians, podiatrists, psychologists, rehabilitation specialists or orthopaedic surgeons. One of the key elements of rehabilitation is patient participation which implies that the patient should be considered as an important member of the rehabilitation team. In daily practice, rehabilitation can be provided in many different ways, depending on the needs of the patient and the organisation and availability of healthcare professionals in the rheumatologist’s working situation. One mode includes the rheumatologist instituting rehabilitative treatment by himself or herself, with involvement of other health professionals in the hospital or in primary care, according to the patient’s problems (eg, give advice on exercise, write a prescription for a wrist splint, or refer a patient to a social worker). If a clinical nurse specialist is available in a rheumatologist’s practice, he or she could play a role in the coordination of this form of care. Another option is rehabilitative care provided by a multidisciplinary team consisting of professionals who are all working in the same rehabilitation centre or a hospital’s rehabilitation unit, under the medical supervision of a rheumatologist and/or rehabilitation specialist. With this form of multidisciplinary team care either group programmes or individual treatment or combinations of both are delivered. Patients with complex problems, complications and/or comorbidity may especially benefit from a comprehensive approach.

The decision on whether or not to refer a patient to a health professional, a rehabilitation specialist and/or rehabilitation team outside one’s own rheumatology unit depends on the nature and complexity of problems encountered and the local availability of rehabilitative services and/or agreements with rehabilitation

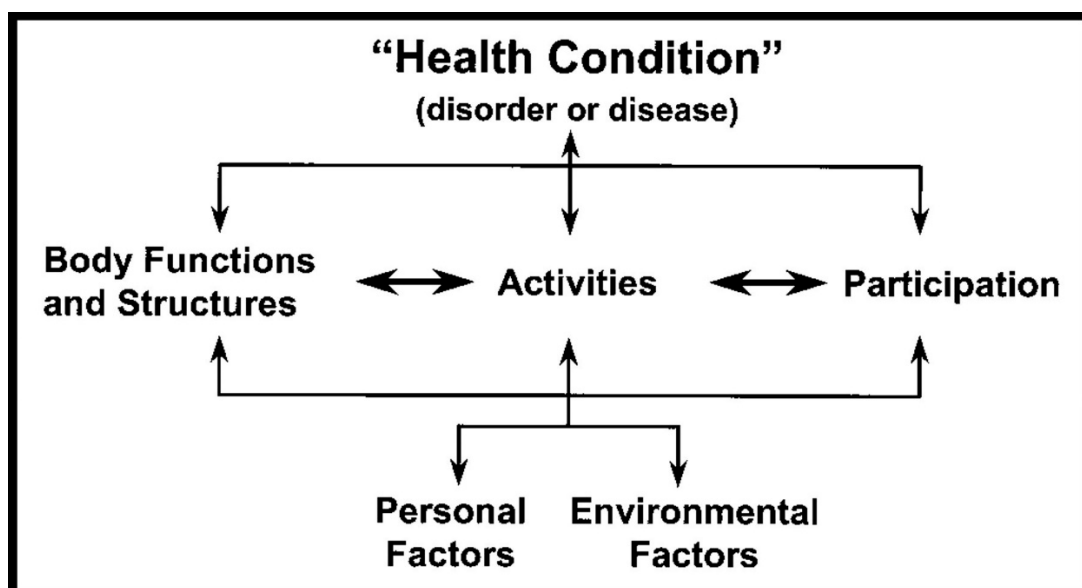

specialists. To make an informed decision, the rheumatologist must be aware of the most relevant problems and needs of the individual patient, and have a good understanding of the potential benefits, risks and limitations of rehabilitative treatment modalities. This includes the consideration of the specific knowledge and skills regarding the treatment of patients with rheumatic conditions of the health professionals involved.

1.2 A structured approach towards rehabilitative management

A structured approach is the key to a successful rehabilitation programme. This should comprise a careful assessment of problems and needs leading to clearly defined individual goals. These goals should lead to identification and provision of appropriate interventions and, finally, an evaluation of goal attainment.

The rehabilitation programme should be designed in close collaboration with the individual patient, to help to reach his or her goals for optimal level of functioning within different areas of disease consequences (figure 2). The World Health Organization International Classification of Functioning, Disability and Health (ICF) offers a useful tool to identify these areas (World Health Organization, 2002; Rauch et al, 2008*). This classification is structured in two parts, with two components in each: (a) functioning and disability (body functions and structures; activities and participation), and (b) contextual factors (environmental factors; personal factors). The following examples may be helpful to understand these concepts: body functions and structures: 'range of knee and hip movements'; activities and participation: 'ability to walk', 'dressing' or 'having a paid job'; environmental factors: 'architectural obstacles' or 'support from family and friends'; and personal factors: 'coping styles' or 'other health conditions'. Identifying the limiting and facilitating factors at each of these levels, and the potential to overcome them, and optimising the use of facilitators, is a key part of the assessment and an essential basis for planning and evaluating the interventions.

Figure 2 World Health Organization International Classification of Functioning, Disability and Health (ICF) model. (Reproduced courtesy of WHO.)

Rehabilitation is organised and managed differently in different countries. However, some key elements of the structure are considered important to improve quality of rehabilitation; there should be a structure for team communication, rehabilitation goals should be defined and evaluated, there should be a structure for patient involvement, and there should be a structure and a plan for follow-up after rehabilitation (Klokke et al, 2012).

2 Rehabilitative treatment modalities

2.1 Physical activity and exercise

Physical activity is defined as ‘any bodily movement produced by skeletal muscles that result in energy expenditure’ (Caspersen et al 1985). The American College of Sports Medicine (ACSM) states that ‘physical activity broadly encompasses exercise, sports, and physical activities done as part of daily living, occupation, leisure, and active transportation’ (*Garber et al 2011). Exercise is a subcategory of physical activity and is ‘planned, structured, repetitive, and purposive in the sense that improvement or maintenance of one or more components of physical fitness is an objective’ (Caspersen et al 1985). Exercise is a cornerstone of the rehabilitative management of rheumatic conditions and the prescription of exercise should take into account the following aspects:

- Objectives (eg, improvement or maintenance of cardiorespiratory fitness, various aspects of muscle functioning (strength, endurance), flexibility and/or specific activities such as walking, climbing stairs).
- The required intensity, number of repetitions and frequency for each type of exercise.
- Limitations and risks of exercises related to the individual patient’s underlying rheumatic condition and health status, including, for example, local joint inflammation, local joint damage, joint instability, the presence of joint prostheses or cardiovascular or pulmonary comorbidity.

Structured exercise programmes for patients with rheumatic diseases usually comprise a combination of exercises to increase cardiorespiratory fitness, muscle strengthening, flexibility and balance exercises, and training of specific movement patterns or daily activities. Exercise programmes can be performed individually or in group, under the supervision of a physical therapist (figure 4) or, after careful instruction, by the patients themselves (figure 3) at home, or by using community-based resources for exercises. The decision on the required nature and extent of supervision depends on the patient’s ability to modify the programme according to fluctuations in his or her health status and to recognise potential side effects of exercises, the physical and social accessibility of exercise facilities and, especially, the qualification of staff/instructors to deal with patients with rheumatic conditions.

Figure 3 Individual exercises, after instruction. Patient consent obtained.

Overall, there is high quality evidence for the effectiveness and safety of exercises in most rheumatic conditions (Sveaas et al 2017; National Collaborating Centre for Chronic Conditions, 2008*; Forestier et al, 2009*; Hagen et al, 2012; Hurkmans et al 2009; Swärdh et al 2016). Suitable forms of exercise are for example walking/hiking, running/jogging, cycling/bicycling, aerobic dance/group exercise, swimming/aquatic exercise, functional exercise, gym machines, rubber expanders or circuit interval training or some combination thereof (Swärdh et al 2016; Sveaas et al 2017; Westby 2001). Public health recommendations on exercise (*Garber et al 2011) can be used in the design of exercise programs for most patients with rheumatic conditions, with appropriate individual adaptations if needed. Rheumatologists have an important task in the education of patients with rheumatic conditions, in particular regarding the role of specific exercises related to individual impairments or limitations and with respect to general physical activity as part of a healthy lifestyle. Moreover, they should refer patients to appropriate professionals or services if they cannot achieve or maintain a sufficient amount of exercise or physical activity by themselves. The evaluation of an exercise prescription should comprise an assessment of its results versus the established goals and the occurrence of side effects, such as persistent pain on exertion or after the exercise sessions.

Figure 4 Supervised exercises. Patient consent obtained.

2.1.1 Public health recommendations on exercise

Evidence based public health recommendations to improve and maintain physical fitness and health states that all adults should perform a program consisting of cardiorespiratory, muscle conditioning, flexibility and balance exercises. Most adults should engage in moderate-intensity cardiorespiratory exercise for ≥ 30 min a day on ≥ 5 days a week for a total of ≥ 150 min a week, OR vigorous-intensity cardiorespiratory exercise for ≥ 20 min a day on ≥ 3 days a week for a total of ≥ 75 min a week, OR a combination of moderate-, and vigorous-intensity exercise. On 2-3 days a week respectively, adults should also perform muscle conditioning, flexibility and balance exercises. It is thus important to design the exercise program based on the individually stated objectives. A gradual progression of exercise volume (duration, frequency and/or intensity) is recommended. People who are unable to meet these recommendations can still benefit from performing less amount than recommended.

2.1.2 Cardiorespiratory exercises

Cardiorespiratory exercises are designed to increase or maintain cardiorespiratory fitness. Any activity that uses large muscle groups, can be maintained continuously, and is rhythmical and aerobic in nature is suitable. Moderate-intensity exercise means that the heart rate and breathing rate of a person is increased, and he or she may sweat but is still able to carry on a conversation. The perceived exertion should be rated 12-13 on a 6-20 RPE-scale (RPE=Rating of perceived exertion) or reach 46-63% VO_{2max} (VO_{2max} =percent of maximal oxygen uptake). Vigorous-intensity exercise means that a person is breathing rapidly and is only able to speak in short

phrases, with his or her heart rate being substantially increased and the person likely to be sweating. The perceived exertion should be rated 14-17 on a 6-20 RPE-scale or reach 64-90%VO_{2max} (*Garber et al 2011).

During the last years, increasing evidence shows that people with inflammatory rheumatic diseases are at increased risk of cardiovascular disease (Castaneda et al 2016, Peters et al 2010). Exercises to maintain or improve cardiorespiratory fitness are in general recommended for all chronic rheumatic conditions. In RA, exercise can have a positive effect on cardiac autonomic function, endothelial function and reduce cardiovascular risk factors (Metsios et al 2014; Stavropoulos-Kalinoglou et al 2013; Janse van Rensburg et al 2012). Patients may have coexisting conditions, such as cardiac or lung disease, related or not to their rheumatic disease. In addition, the presence of joint prostheses or other specific joint conditions may require the minimisation of some weight bearing activities and/or the avoidance of specific sports. In these cases expert advice from a cardiologist, pulmonologist or orthopaedic surgeon, and appropriate modification and careful supervision of the exercise programme, are needed.

2.1.3 Muscle conditioning exercises

Muscle conditioning exercises are designed to maintain or improve various aspects of muscle functioning, such as strength and endurance. A muscle conditioning exercise programme should include 8–10 strength-training exercises for major muscle groups, with 8–12 repetitions of each exercise, in 2-4 sets. An intensity between 20-80% of 1RM (RM=repetition maximum) depending on objective, experience and age is recommended (Garber et al 2011). The selection of exercises for therapeutic purposes depends on the specific impairments at the level of body functions and structures or on limitations in activities and participation of the individual patient. Dynamic muscle conditioning exercises should be used with caution in cases of unstable or mal-aligned joints, whereas isometric (static) muscle conditioning exercises may increase blood pressure.

2.1.4 Flexibility exercises

Flexibility exercises are prescribed to develop and maintain ROM within physiological limits. In general, flexibility exercises should include the joints most relevant to function and may preferably, in most rheumatic diseases, be performed daily (Garber et al 2011). Flexibility exercises are especially important in the case of local joint inflammation and pain, when there is a risk of developing contractures. Flexibility exercises are not to be prescribed in the case of joint instability, in particular of the spine (eg, cervical subluxation in patients with rheumatoid arthritis (RA)) or if a fracture is suspected (eg, osteoporotic fracture of the spine in patients with ankylosing spondylitis (AS)).

2.1.5 Balance exercises

Balance exercises are prescribed to reduce the risk of injury from falls in patients with rheumatic conditions who have a substantial risk of falls. Balance exercises may comprise standing-in-place exercises, either

combined or not combined with the use of a balance board, muscle strengthening exercises or gait training, or activities such as dancing. Tai chi is a popular form of alternative or complementary medicine which aims, among other goals, to improve or restore balance. Although the evidence for its effectiveness in rheumatic conditions is limited, conditional recommendations for tai chi in knee osteoarthritis have been issued (Hochberg et al 2012). Balance exercises are in general considered to be safe; however, a careful evaluation of the cause of balance problems and falls (eg, neurological or cardiac) is needed before their prescription.

2.2 Patient education and self-management support

Patient education has been defined as: ‘a planned learning experience using a combination of methods such as teaching, counselling, and behaviour modification techniques which influence patients’ knowledge and health behaviour’. Patient education can be provided individually or in groups. It is an interactive process assisting patients to participate actively in their health care, and providing them with information about available health services and their use (figure 5). Active participation in health care and effective self-management implies, for example, adherence to medication and exercises, and the use of orthoses or assistive devices and ergonomic techniques. Self-management support means providing education and supportive interventions to increase patients’ skills and confidence (i.e self-efficacy) in managing their rheumatic disease. This support is the responsibility of health care providers, however self-management skills, meaning performing the behaviours necessary to manage and live well with the rheumatic disease, is the responsibility of the patient (Brady et al 2006). Difficulties in applying these skills can have a decisive impact on a patient’s response to therapy and quality of life. The EULAR recommendations for patient education emphasizes patient education as an integral part of standard care (Zangi et al 2015). The proficient rheumatologist will be sensitive to these difficulties and provide advice or seek the assistance of a rehabilitation specialist or other professional if needed.

Figure 5 Individual patient education. Patient consent obtained.

Structured patient education in rheumatic diseases is based around three areas: (a) knowledge; (b) skills and behaviour; and (c) psychosocial support and coping (table 1).

With respect to knowledge, patients need an understanding of the basic concepts of anatomy and inflammation, as a prerequisite to understanding the objectives, limits and risks of drug therapy and non-pharmacological strategies such as exercises, activity pacing or weight reduction. In addition, patients need to understand the roles of the various healthcare providers involved in the management of their condition and, especially, acknowledge the importance of their own role in the management of their disease. Knowledge translation is enhanced if simple, non-threatening language is used, and written information is available for later review.

Self-management skills include specific behaviours, such as medication use, daily exercise regimens, the application of activity pacing techniques, and the usage of ergonomic techniques and adaptive devices.

The psychosocial and coping area pertains to helping patients feel more confident in being able to manage their rheumatic condition and to function in the conduct of daily tasks, thereby reducing feelings of anxiety, depression and helplessness.

Table 1 Content areas of structured patient education

Content area	Examples of specific content
Knowledge	<p>Anatomy, disease process, inflammation and risk of comorbidity</p> <p>Symptoms and signs of improvement or deterioration in rheumatic condition; understanding of disease monitoring</p> <p>Drug therapy: usage, effects, side effects</p> <p>Knowledge of activity pacing, aids, assistive devices, orthoses and ergonomic techniques to maximise function</p> <p>Understanding the benefits or risks of surgical interventions</p> <p>Health benefits of exercise and physical activity</p> <p>Understanding of where to find health professionals, community resources, patient/consumer organisations</p>
Skills and behaviours	<p>Performing exercises and achieving a sufficient level of physical activity</p> <p>Seeking insight into his/her own capacity and, through activity pacing, finding the individual balance between pain, fatigue and activity</p> <p>Making daily tasks easier by using adaptive devices, home or work adjustments, or using altered working methods</p> <p>Medication adherence and monitoring of side effects</p> <p>Seeking medical support in case of symptoms of drug side effects</p>
Psychosocial and communication dimensions	<p>Reducing anxiety and feelings of helplessness, increasing confidence for specific tasks or roles</p> <p>Communicating with healthcare providers, learning how and when to ask questions</p> <p>Eliciting support from partner or other family members</p>

Overall, there is high quality evidence for the effectiveness of educational interventions in patients with RA and osteoarthritis (OA) (Iversen et al 2010*; Knittle et al 2012), and to a lesser extent in AS (Vliet Vlieland and Li 2009) or other rheumatic conditions. The rheumatologist is in a strategic position to engage in patient education as part of his or her medical consultation. In case there is a need for additional education, this may be provided by other individual health professionals such as nurses, social workers, physical therapists, occupational therapists or psychologists. Patient education can also be provided by trained patients (patient partners). Patient education may also be provided in a group setting, either ancillary to medical care or in the community. It is also important for the rheumatologist to provide brief behavioural counselling to enhance patients' self-management skills. Rheumatologists have the opportunity to assess the patients' behaviour and beliefs, advice and provide information, use collaborative goal-setting, facilitate an action plan and arrange follow-up (Brady et al 2006).

2.2.1 Educational interventions promoting optimal function in everyday life activities

Educational interventions promoting optimal function in everyday life activities (known as joint protection) attempts to help patients plan, pace and carry out activities in such a way that pain is minimised and their energy level is maximised. Simple measures including performing tasks at a slower pace and breaking activities into smaller sections with periods of rest in between, proper body positions, adaptation of the work environment, and use of assistive devices can have a huge impact on the work load. Such measures can make a very important contribution towards reducing fatigue and pain, and increasing the patient's productivity and satisfaction.

The main guiding principles include the avoidance of positions and activities that are stressful for joints and cause pain and discomfort by using alternative body positions, working heights and working methods, using assistive devices, and finding the right balance between rest and activity. Evidence for the effectiveness of educational interventions promoting optimal function in everyday life activities (joint protection and energy conservation) is mainly available for RA (Steultjens et al 2004). In other rheumatic conditions the evidence is scarce (Stamm et al 2002; Spadaro et al 2008). The term 'joint protection' should be used with caution, as it reflects the opposite of what is desirable to communicate: the importance of keeping up activity and exercising to maintain movement and strength.

2.2.2 Aids and devices and adaptations of physical environment

Aids and devices and adaptations of physical environment can be used to ease pain, overcome joint limitations, compensate for muscle weakness, and enhance safety. The ultimate aims are to relieve suffering and increase function and independence.

There is a large variety of assistive devices to address the individual needs of patients in almost all areas of activity: personal care and protection, mobility, housekeeping, furnishing and adaptation of homes and other premises, communication, information and signalling, recreation, etc.

The interested rheumatologist can and should provide patients with useful advice in this respect, as it is an integral and important part of the management programme. If available, the patient should be referred to an occupational therapist or a physiotherapist for a more extensive consultation related to adaptations and information on assistive devices. Table 2 provides examples of activities, related aids, and assistive devices and home modifications relevant for rheumatic conditions.

With respect to upper extremity aids, pinch and grasp can be improved by building up handles on tools, cookware and eating utensils (figures 6 and 7). Grip can further be improved by using no-slip mats or cutting boards (figure 8). Power equipment, such as electric knives and tools, can substitute for decreased power grip and poor upper extremity strength. Reachers (figure 9) can be used to retrieve objects from floors and shelves. Long-handled brushes, combs and sponges can help with upper extremity grooming and perineal care. Buttonhooks, zippers with tabs, clothing and shoes with Velcro closures, elastic waist trousers, and V-neck pullovers can facilitate dressing. Sock cones and long-handled shoehorns ease the donning and doffing of socks and shoes, and dressing sticks assist those with impaired shoulder mobility.

Figure 6 Utensil with enlarged grip.

Table 2 Examples of assistive devices and adaptations to homes and furnishing (Adapted from Noaker JA. Enhancing functional ability: alternative techniques, assistive devices and environmental modification. In: Wegener ST, Belza BL, Gall EP, eds. Clinical care in the rheumatic diseases. Atlanta, Georgia: American College of Rheumatology, 1996)

Activity	Example of assistive device or adaptation
Personal hygiene	Enlarged-handle brush/comb Long-handled brush/comb Wash and dry bidet
Bathing	Long-handled bath sponge or brush Shower chair Bathtub seat–elevator Replacing bath with walk-in-shower
Dressing	Sock device Long-handled shoe horn Elastic shoe laces Replace closures with Velcro
Eating	Enlarged handle grips or cylindrical foam Rocker or angled knife Non-slip matting under plate
Transfers and mobility	Lift chair Elevated toilet seat or chair Grab bars Canes, crutches Rolling walker Electric mobility scooter (Electric) wheelchair Bicycle with electric support
Household	Loop scissors Reacher Electric can opener Long-handled non-wringing sponge or mop Tools with enlarged and cushioned handles Non-slip mats
Work and school activities	Large diameter pens Document holder Speaker phone or headset Ergonomic keyboard
Leisure activities	Gardening tools with cushioned handles Playing card holder

Figure 7 Utensil with bent and enlarged grip.

Figure 8 No-slip cutting board.

Figure 9 Reacher.

Concerning the lower extremity, rheumatologists ought to have some knowledge of canes, crutches and walkers, as they will be frequently used by their patients. These aids are aimed at improving gait and ease weakness, pain and instability in lower extremity joints.

Most assistive devices can usually be found by local suppliers or on the internet. The selection of the best tool will be more appropriately performed by the patient with the support of a trained professional, who will have specimens of various devices in his or her practice. If the rheumatologist provides assistance, a number of factors should be considered before advising on aids and assistive devices, including physical, social-emotional,

environmental, and financial factors (table 3). This consideration also includes potentially negative consequences of the use of assistive devices, such as making the physical disability more obvious for other people or the implicit idea that activities should be avoided because they could be harmful.

Overall, the literature on the effectiveness of adaptive devices is scarce (Tuntland et al 2009). Permanent and drastic adaptations to the home should always be carefully considered, and mainly be advised in case no improvement of the patient's health status can be expected in the short term.

Table 3 Factors to be considered in prescribing assistive devices (Adapted from Noaker JA. Enhancing functional ability: alternative techniques, assistive devices and environmental modification. In: Wegener ST, Belza BL, Gall EP, eds. Clinical care in the rheumatic diseases. Atlanta, Georgia: American College of Rheumatology, 1996)

Physical factors	Effects on pain, stiffness and joint stress Effects on energy and time expenditure Convenience (eg, easy to do, on/off) Frequency of use Substitution of activities
Social-emotional factors	Effect on independency in activities of daily living Cosmetic aspects Learning ability to use device
Environmental factors	Compatibility with environment of home/workplace Aspects with regard to instalment and maintenance of equipment
Financial factors	Commercial availability Insurance policies

2.3 Orthoses

The term 'orthoses' refers to 'any medical device added to a person's body to support, align, position, immobilise, prevent or correct deformity, assist weak muscles, or improve function'. In rheumatic conditions orthoses are usually used to relieve pain through reduction of strain or load on a joint or a decrease in its motion. They can also be used as a conservative modality to improve patterns of motion, or postoperatively to provide stability and ensure healing in an optimal position. Postoperative orthoses can both be static and dynamic. Orthoses are most commonly made or tailored by occupational therapists or prosthetists.

The aims of splints and the advised duration of their use should be communicated clearly to patients. Moreover, patients with rheumatic conditions may have more fragile skin due to their disease or to medications. Splint fitting, padding and lining can address this issue. The effects of immobilisation on the targeted joint, as well as adjacent joints, should be considered when prescribing splint wear. In all cases, splints should be removed periodically for ROM exercise and skin care.

The following sections present a core summary of important concepts that the rheumatologist should master regarding the most commonly used orthoses in his field.

2.3.1 Wrist orthoses

Wrist orthoses provide support for the wrist while allowing motion of the thumb and fingers. Indications for a wrist splint include wrist pain and synovitis or tenosynovitis (Adams et al 2005). Different types of wrist splints are available. Functional or working wrist splints permit movement of the metacarpophalangeal (MCP) joints and the finger joints. Working wrist splints are intermittently used during activities in which resistance, object weight or protracted positioning are likely to stress the wrist, with the aim of supporting joints and restricting motion; they are primarily thought to relieve pain and improve the performance of activities of daily living.

With resting splints, the MCP and finger joints are also immobilised, and these splints are to be worn intermittently during resting periods over the day and at night. Resting wrist splints are mainly prescribed to reduce pain and other signs of inflammation, and to a lesser extent to prevent contractures and preserve function.

A systematic review from 2014 concludes that working wrists splints reduce pain and improve grip in RA, but the effect on function is unclear (Ramsey L et al 2014)

With wrist splints, for most conditions, a functional position of 20° to 30° of extension of the wrist while wearing the splint is advocated, with the exception of carpal tunnel syndrome, where 10° extension is recommended. Wrist working splints have been found to reduce wrist pain during activities, but may also decrease dexterity and interfere with some daily activities such as working in water or in dirty conditions (eg, gardening). With the prescription of wrist splints, the potential benefits and adverse effects need to be discussed with the patient.

2.3.2 Finger orthoses

Finger orthoses are prescribed in the case of finger deformity or instability such as swan neck or boutonnière deformities in patients with RA. These deformities may interfere with pinch grip and fine precision activities. A swan neck splint prevents the proximal interphalangeal joint from hyperextension while supporting the volar surface (figure 10), whereas a boutonnière splint places the proximal interphalangeal joint in extension (van der Giesen et al 2009). Finger splints can be made from sterling silver or thermoplastic material, with no differences in effectiveness related to the material they are made of. Side effects of finger splints include pressure on bony edges, the development of rheumatoid nodules in RA patients, or paraesthesias in the finger tips.

Figure 10 Finger splints for swan neck deformity.

2.3.3 Thumb splints

The thumb accounts for 60% of hand function. When thumb movement is limited by pain, instability or deformity, hand function is greatly reduced. A common condition where thumb involvement is seen is OA of the first carpometacarpal joint. This condition is often associated with instability and pain, particularly during activities in which force is exerted by the thumb (eg, in applying pinch or three-point grip). In this case, a thumb support either covering both the thumb base and wrist or protecting only the thumb base can improve pain and function (Ye et al 2011*). The thumb should be placed in a functional position of opposition to the index finger. In addition, wrist and thumb interphalangeal joint motion should not be restricted (figure 11).

Figure 11 Thumb base splint.

Involvement of the MCP joint of the thumb can be seen in patients with RA. Splints to support the MCP joint of the thumb can improve pinching abilities by providing support and relieving pain. A so-called 'figure of eight' splint for this joint allows movement of the carpometacarpal and interphalangeal joints while providing lateral support and positioning the MCP joint for function.

Splints for hyperextension and lateral instability of the interphalangeal joint of the thumb follow the same guidelines as for the proximal interphalangeal joints of the fingers.

2.3.4 Knee braces

In particular in patients with knee OA, pain and disability may be due to an abnormal distribution of forces as a result of malalignment (varus or valgus). Knee braces are applied with the aim of decreasing pain by reducing the load in one of the compartments of the knee. Moreover, they can improve stability and diminish the risk of falling (Brouwer et al 2005). Knee braces are made of combinations of metal, foam, plastic, elastic material and straps. They are available 'off the shelf' or by manufacture of an individualised brace. As many patients benefit from off-the-shelf knee braces such as sport braces in daily rheumatological practice, the prescription of custom-made braces for knee OA should be carefully considered. It should be noted that their cosmetic aspects, difficulties with putting them on and off, lack of comfort while wearing them, and interference with clothing may affect adherence.

2.3.5 Footwear

Appliances for the rheumatic foot are prescribed to relieve excessive pressure, to reduce shock and shear, to accommodate, correct and support deformities, and to control or limit painful motion of joints (Rao et al 2012).

Prescription footwear is made according to practitioner-prescribed specifications. External shoe modifications may consist of rocker soles, extended steel shanks, stabilisers, wedges or extensions (figure 12). Inserts may comprise soft, semi flexible or rigid insoles or toe wedges. Custom-made in-shoe devices may be moulded or milled from an impression of the foot (eg, a plaster cast or three-dimensional laser scan).

Apart from prescription footwear, off-the-shelf footwear for those with arthritis, to which orthopaedic amendments often can be made, is readily available (figure 13).

Figure 12 Custom-made shoes with a metatarsal bar underneath.

Figure 13 Off-the-shelf footwear with elastic leather upper.

2.4 Electrophysical modalities

Under this designation we include a range of modalities including electrical, thermal, light, sound and magnetic energy, mainly used to promote positive effects upon body functions and structures, but also to facilitate the performance of physical activity and exercise.

2.4.1 Heat and cold therapy

Heat is mainly prescribed for muscle relaxation, to reduce stiffness and to improve local circulation. It may be administered in the form of superficial heat (hot packs, paraffin or wax baths, thermal baths and infrared) or deep heat (electromagnetic wave forms and ultrasound). The main goals of cold therapy are to reduce pain and decrease swelling. It is applied by means of ice packs, ice chips, ice massage, cryowraps, cold air, vapocoolant sprays or whole-body cryotherapy.

Overall, the evidence for the effectiveness of heat and cold therapy in rheumatic diseases is scant. A beneficial effect of heat (paraffin) on ROM, hand function, pain and stiffness has been reported in patients with RA (Robinson et al 2002), whereas cold therapy was found to have a positive effect on ROM, function, strength or swelling in knee OA (Brosseau et al, 2003). Both superficial heat and cold therapy need to be used with caution, as they may cause dermal injury, in particular in patients with reduced sensibility (eg, diabetic neuropathy) or peripheral vascular disease. Moreover, both superficial heat and deep heat are usually advised against in the case of local joint inflammation, as both have been found to increase the intra-articular temperature.

2.4.2 Electrotherapy

Electrotherapy consists of the therapeutic use of different forms of electric currents, mostly applied by surface electrodes. The main clinical indications are pain control and muscle stimulation. The most common form of

therapeutic electrical stimulation used for pain control is transcutaneous electrical nerve stimulation (TENS), which can be applied in case of loco-regional pain. TENS devices are small, portable instruments, producing sharp impulses (0.2 ms) within a frequency range of 1–150 Hz. The patient can activate and control intensity as needed after appropriate instruction (figure 14).

There is low quality evidence for the effectiveness of TENS in RA and moderate quality evidence that TENS reduces pain in knee OA. The electrodes of TENS devices may occasionally cause skin irritation. Moreover, it is recommended that TENS is not applied over the anterolateral aspect of the neck, to avoid vagal stimulation. In addition, people with pacemakers are advised not to use TENS near the heart.

Figure 14 TENS intervention for the knee. Patient consent obtained

2.4.3 Laser therapy

Low level laser therapy was introduced for the treatment of rheumatic diseases in the 1980s. It uses a light source that generates extremely pure light of a single wavelength. Low level laser therapy aims to decrease inflammation, with its mechanism not being thermal but rather related to photochemical reactions in the cell. There is moderate quality evidence that low level laser therapy applied to the hands reduces pain and morning stiffness in patients with RA, and that low level laser therapy applied to the knee reduces pain in patients with knee OA.

2.5 Spa therapy

Bathing in water (spa therapy, balneotherapy or 'passive' hydrotherapy) is still very popular in some parts of the world, including Europe, not only in patients but also among the general population. Water from mineral and thermal springs has been particularly valued, although evidence for the impact of the qualities of the water is scarce. Balneotherapy can include a variety of modalities, such as radon–carbon dioxide baths, carbon dioxide baths, Dead Sea baths or sulphur baths. Balneotherapy is best tolerated with temperatures of around 34°C and a duration of about 20 min (Verhagen et al 2012). The aim of balneotherapy is to improve the range of joint motion and muscle strength, relieve muscle spasm, maintain or improve functional mobility, soothe pain and, as a consequence, relieve patients' suffering and improve their well-being. Balneotherapy is often combined with other treatment modalities, in particular exercise programmes, with comprehensive programmes usually having a duration of 2–3 weeks. Overall, there is low quality evidence for the effectiveness of balneotherapy in RA, OA or AS (Verhagen et al 2003; Verhagen et al 2008; Verhagen et al 2012). As combined spa-exercise programmes are most commonly provided in a health holiday setting, it remains unclear to what extent the setting contributes to their perceived benefit.

2.6 Vocational rehabilitation

The importance of work to patients goes well beyond their economic needs; it may have a decisive impact upon their overall quality of life. The rheumatologist has an important role in identifying working problems by asking patients on a regular basis to what extent and how their rheumatic condition has influenced their work ability and working status. In case of a working problem, the rheumatologist may refer a patient for vocational rehabilitation (VR). VR can be defined as 'a process to overcome the barriers an individual faces when accessing, remaining or returning to work following injury, illness or impairment'. It may encompass a broad range of interventions, beyond medical and non-pharmacological management of the condition: assessment of needs, work adjustment and control measures, staged return-to-work management, disability awareness training, retraining and capacity building, and support for the individual, employer or others (box 1). With respect to referrals for VR, it will depend on the healthcare system and/or social security system in a specific country as to which professional or which service within or outside the healthcare system is most suitable. In some countries occupational therapists provide individual consultations regarding work related problems (Macedo AM et al 2009). A systematic Cochrane review assessing the effects of non-pharmacological interventions aiming to prevent job loss, work absenteeism or improve work functioning in persons with inflammatory arthritis found that there was a potential for positive long term results. These interventions should include an analysis of a person's work activities, work functioning assessment of ergonomic needs and communication at work to identify those features of working life that are placing the person at risk of dropping out of work (Hoving JL et al 2014). Comprehensive work interventions may have positive psychological effects, as well as result in increased work participation (Cignac et al 2012*). Some studies report favourable results in

the early stages of work disability, including the perception of any working problems by the patient while working (work instability) or the occurrence of sick leave (Allaire et al 2003). Currently data are insufficient to identify patients at risk for work disability and to determine the optimum time to intervene (Cignac et al 2012*), but the high personal and socioeconomical cost of sick leave provides a strong argument for early identification of problems, and early interventions.

Box 1 Examples of vocational rehabilitation strategies to enhance job retention

Employee

- Changing medication regimens; good symptom control
- Pacing: taking more rest breaks and microbreaks
- Work simplification, ensuring immediate work area is ergonomically structured
- Using splints, assistive devices and equipment adaptations
- Increased planning of work tasks, changing work tasks
- Informing employer and/or colleagues about disease and functional ability/disability
- Appropriate help-seeking from colleagues
- Altering working hours, decreasing days
- Transport changes
- Changing jobs

Employer

- Providing special equipment, environmental modifications and access to disabled parking
- Job flexibility (flexible working time, task variation, reducing time pressure)
- Better understanding of rheumatic conditions

Employee and employer

- Timely usage of VR services
- Good working relationships between employee/patient, employer and colleagues
- Knowledge of the rights of people with disabilities and employers' responsibilities to such people

Adapted from Hammond, Best Pract Res Clin Rheumatol 2008;22:435–49.

3 Rehabilitation in specific rheumatic conditions

In this section we will provide a short overview of the most common rehabilitation needs and opportunities related to a number of specific rheumatic conditions, underlining the possible role of rheumatologists and the potential contribution of specialised professionals.

3.1 Rheumatoid arthritis (RA)

Similar to the monitoring of disease activity, the rheumatologist plays an important role in the monitoring of the patient's functioning in daily activities and also societal participation during the course of the disease. For standardised monitoring of functional disability, the Health Assessment Questionnaire is often used, including 20 items on physical function and also querying help from another person or use of devices. Although this questionnaire does not address level of participation, including work disability, the HAQ score could be used as a screening tool for assessing the need of comprehensive multidisciplinary assessments of the components of

disability and corresponding interventions (Thyberg et al 2012). Despite the availability of many effective drugs (such as synthetic and non-synthetic disease modifying drugs) for the treatment of RA, limitations in daily activities and/or restrictions in participation are still a consequence of living with RA for many patients. While some patients experience limitations already for performing basic daily activities, more often challenges are related to performing complex actions, including work (paid or unpaid) and leisure activities. Moreover, the prospect of living with a chronic disease and being in need of medication places an emotional burden on patients which is sometimes underestimated. For patients experiencing any limitation in their functioning, there are a number of rehabilitative interventions to be considered as an adjunct to pharmacological therapy.

3.1.1 General rehabilitative management

In general, exercise and patient education are the cornerstones of the rehabilitative treatment of RA patients, and access to a multidisciplinary team is considered to be a part of the standard care for patients with RA in many countries.

With respect to exercise, most research in RA has so far focused on dynamic exercises (exercise with the aim of improving cardiorespiratory fitness and/or muscle strength). It has been consistently demonstrated that in patients with RA dynamic exercises, either supervised and/or home-based, are effective with respect to improvement in aerobic capacity and muscle strength, with no detrimental effects on disease activity or pain, or radiological damage (Hurkmans et al 2009; Swärdh et al 2016). There are also results indicating that physical activity and exercise has significant effect upon self-reported fatigue in RA patients (Rongen-van Dartel et al 2015; Cramp et al 2013), and can improve sleep quality (Durcan 2014). It is important to underline that, contrary to a rather common belief, exercising inflamed joints does not have any deleterious effects.

Given these health benefits, RA patients should be advised to maintain an amount of physical activity that at least equals public health recommendations. If a patient cannot achieve this goal on his or her own—due to, for example, local disease activity or joint damage, comorbidity, inability to modify exercises according to disease fluctuations or movement anxiety, and/or if there are limitations in specific movement patterns or daily activities that need to be addressed—then this is an indication for guidance and supervision by a physical therapist.

In RA, a substantial number of studies have consistently demonstrated small, short-term beneficial effects of a broad range of psycho-educational interventions on health status (pain, functional disability, fatigue, psychological well-being and disease activity) (Iversen et al 2010*; Knittle et al 2010; Knittle et al 2012; Cramp et al 2013). Sustained effects of psycho-educational interventions have been reported in studies where CBT was administered, in particular early in the course of RA or in patients with a psychosocial risk profile (Evers et al 2002). So far, the optimal composition and timing of psycho-educational interventions in RA have not been established, but factors enhancing their effectiveness and/or maintenance include: a duration of at least 6

weeks; explicit use of cognitive behavioural approaches; individualised weekly action plans with progress review; the usage of protocols and participant handbooks; provision by the same trained leaders; and the employment of intervention techniques derived from the self-regulation theory (Iversen et al 2010*; Knittle et al 2010). With respect to educational interventions promoting optimal function in everyday life activities (joint protection) and energy conservation in particular, the literature provides evidence for the effectiveness of structured programmes, mainly delivered by occupational therapists, on functional ability (Steultjens et al 2004). Evidence for the effectiveness of assistive devices was found to be scarce (Tuntland et al 2009). However, daily experience as well as high rates of possession and usage in epidemiological studies suggest their benefit for many RA patients. In case it is not clear which assistive device would be the best solution for a patient's functional limitation, or when there is a need for individually manufactured devices or large adaptations to the home, referral to a rehabilitation specialist, occupational therapist or nurse specialist (depending on the complexity of the situation and the availability of professionals or services) must be considered.

3.1.2 Management of hand problems

Wrist pain is common in RA patients. Hand exercises have been shown to be both effective and cost-effective in RA (Lamb et al 2014). In addition to advice on appropriate assistive devices, wrist splints can be considered. As regards the type of splint, working wrist splints are especially recommended, as the literature suggests that these may improve pain and strength during the performance of activities (Veehof et al 2008), whereas no beneficial effects of resting wrist splints have been documented in RA (Adams et al 2005). In case of swan neck and/or boutonnière deformities, finger splints may be considered with the aim of improving finger stability and correcting the deformity, thereby improving dexterity. Their effectiveness has been established in a number of studies in RA patients (Zijlstra et al 2004; van der Giesen et al 2009). With the prescription of every type of splint, careful advice, including on the aim of the splint, joint position, wearing times and skin care, and an evaluation of the effect should be provided.

3.1.3 Management of foot problems

RA patients' feet and walking ability are often not adequately considered, although foot involvement is present in the majority of patients.

In patients with RA, it was found that extra-depth shoes decrease pain during weight bearing activities such as standing, walking and stair climbing. Furthermore, it was concluded from a systematic review that in patients with RA, custom-made foot orthoses reduce pain and forefoot pressure (Hennessy et al 2012). Foot orthoses may improve pain in patients with RA, but their impact on disability is unclear (Conceição CS et al 2015). Moreover, research in patients with RA and OA with painful hallux valgus found that custom-made foot orthoses reduced foot pain; however, there was no benefit in comparison with surgery.

3.1.4 Management of cervical spine problems

Cervical spine orthoses are predominantly prescribed for patients with RA and atlantoaxial (C1–C2) subluxation. In these cases, the aim of a cervical spine orthosis is to limit motion of the cervical spine, especially flexion, thereby reducing pain, muscle tension and paraesthesias, and the risk of spinal cord injury. There are different types of cervical spine orthoses, varying with respect to their shape, material, extent and localisation of points of support, and comfort. Wearing cervical spine orthoses, in particular hard cervical collars, is considered uncomfortable by many patients, due to problems of heat and difficulties with eating, dressing, washing oneself, and getting the collar on and off.

Concerning the effectiveness of cervical spine orthoses in RA, some studies suggest that flexion of the cervical spine is indeed limited, especially when wearing a stiff cervical collar, whereas in other studies stabilisation of cervical motion was unsatisfactory. An effect of cervical spine orthoses on the progression of C1–C2 subluxation in RA has not been demonstrated. A cervical collar can promote muscle relaxation and may be effective for pain relief in individual patients with non-specific cervical pain syndromes.

3.2 Spondyloarthritis (SpA)

Most of the general recommendations on exercise and patient education in RA patients are applicable to patients with SpA (including ankylosing spondylitis (AS)). There is a growing consensus that an exercise programmes for patients with SpA should be vigorous and include flexibility, strengthening and cardiorespiratory components. Flexibility exercises are particularly aimed at maintaining or improving spinal mobility, chest expansion and the ROM of peripheral joints (hip and shoulder motion) and to decrease symptoms of stiffness. Postural muscles, especially in the thoracic spine, and gluteal and quadriceps muscles should be conditioned. A cardiorespiratory component is needed because of the risk of restrictive pulmonary involvement. In addition to exercises, patients need information and guidance regarding improvement and maintenance of appropriate body positions during work (in or out of the home), leisure, sleeping and driving.

Given the increased risk of fractures, passive mobilisation of the spine of the patient with axial SpA is dangerous and should never be advised or performed.

Changing position and flexibility exercises should be carried out frequently. Patients with SpA should be referred to a physical therapist for postural guidelines and instruction on an exercise regimen that should be performed by the patient on a daily basis. Participation in weekly group or sports activities for patients with SpA should be recommended to enhance adherence.

In patients with AS, a beneficial effect of exercise programmes, including strengthening, cardiorespiratory exercises, hydrotherapy, sports activities and stretching, on spinal movement has been consistently demonstrated (van den Berg et al 2012*; O'Dwyer et al 2014*). The evidence was moderate concerning the

effect on physical function, disease activity and chest expansion, and low-level concerning pain, stiffness, spinal mobility and cardiorespiratory function. Overall slightly more favourable results were seen with supervised exercises than with individualised home exercises (O'Dwyer et al 2014*).

With respect to education, the patient with AS is advised to comply with a number of recommendations, including medication use, exercise, and modification of working methods or of the environment. When the evidence on the effectiveness of education in this patient group was considered, it was found that energy conservation and educational interventions promoting optimal function in everyday life activities (joint protection programme) as an adjunct to treatment with anti-tumour necrosis factor α (anti-TNF α) agents was beneficial, with synergistic effects on pain, function and disability (Spadaro et al 2008).

Techniques and devices may be needed to compensate for the lack of spinal, cervical, hip or shoulder movement. Devices considered very useful in this patient group include long-handled dressing aids, reading stands, elongated rear view mirrors and lumbar back supports. Patients should use as few pillows as possible, but at least one is needed to support the head and cervical lordosis. In AS, common sites for enthesitis are under the heel, where the plantar fascia attaches, and behind the heel at the Achilles tendon insertion. Shoe inserts that relieve localised pressure under the heel or raise the hind foot can relieve pain in these cases.

Inpatient rehabilitation has also proven to be efficient for increased function and reduced pain (van den Berg et al 2012*).

3.3 Osteoarthritis (OA)

The main components of non-pharmacological treatment in OA are education, exercise and weight reduction (Hochberg et al 2012). The provision of oral and written information about the disease, its course and pharmacological treatment is important. Patients should also be informed about the use of adaptive devices and orthoses, 'pacing' of activities, and a healthy lifestyle (physical activity, reducing overweight). Moreover, the limited potential benefits and side effects of thermotherapy or TENS in addition to these interventions should be highlighted (Palmer et al 2014). Education on all of these topics is the starting point for any self-management intervention for OA in one or more joints. Exercise should, apart from general improvement of cardiorespiratory fitness and muscle strength, focus on the reduction of local joints impairment (eg, local muscle weakness, limited ROM) in order to improve the performance of daily activities.

3.3.1 OA of the hip and/or knee

OA of the hip and/or knee is likely to be associated with reduced muscle strength, reduced knee joint proprioception, impaired balance and an increased risk of falls. In addition to the advice of attaining and maintaining an active lifestyle by meeting public health recommendations on physical activity, cardiorespiratory exercises and muscle strengthening exercises (gluteal and quadriceps muscles), in

combination with flexibility and walking exercises, are recommended for OA of the hip and/or knee. In patients with both knee and hip OA, a positive effect of land-based exercise programmes on pain and function has been consistently demonstrated. Additional 'booster' sessions provided after the treatment period appear to positively influence the duration of the effect (Pisters et al 2007; Hernandez-Molina et al 2008).

In overweight or obese patients, advice or counselling on weight reduction may contribute to a decrease in the mechanical load on joints, thereby lessening pain and improving function.

The use of walking aids may reduce pain in patients with hip and knee OA. Moreover, based on expert opinion, patients with hip and knee OA are generally advised to wear shoes with thick but soft soles, and no raised heels. Laterally or medially wedged insoles are sometimes recommended in patients with medial or lateral tibiofemoral OA, respectively. In patients with knee OA and instability and/or malalignment, a knee brace can be considered, with the aim of reducing pain, improving stability and reducing the risk of falling. Taping of the patella (ie, applying adhesive, rigid, strapping tape to glide, tilt and/or rotate the patella to pull it medially) can be used to modify patella position. This intervention might be considered in chronic knee pain resulting from either anterior knee pain or patellofemoral OA. Although positive effects of taping the patella in chronic knee pain are reported, no firm conclusions can be made with respect to the optimal direction (medially or laterally) (Warden et al 2008). Self-care activities may be facilitated by the use of assistive devices such as raised toilet seats or chairs, grab bars or shower seats. In the case of complex problems or OA in multiple sites, consultation with a rehabilitation specialist or occupational therapist is likely to be beneficial.

3.3.2 Hand OA

As part of the management of hand OA, a patient should be advised on pacing of hand use, and to avoid repetitive power grip, pinch and twisting movements. Education combined with exercises have been found to improve functional outcomes in hand OA more than information alone (Hennig et al 2014). A Cochrane review evaluating the effect of hand exercise in hand OA concludes that exercise has small beneficial effects on hand pain, function and joint stiffness (Østerås et al 2016).

Instability and pain of the first carpometacarpal joint, particularly during activities in which force is exerted by the thumb, can be counterbalanced by a thumb splint (Ye et al 2011*). In addition, numerous assistive devices, including, for example, enlarged grips on pens and cutlery, and electric can openers can be very useful.

3.4 Regional musculoskeletal pain syndromes

Under this heading we refer to a number of conditions including tendinitis, tenosynovitis, bursitis, and ligament strains (Speed and Hunter 2007). Space does not allow a detailed description of rehabilitative methods applicable to the different conditions. However, a few basic principles can help the rheumatologist to achieve good results in these common conditions.

With musculoskeletal pain syndromes, the key to successful rehabilitative management includes ensuring that the patient has a full understanding of the disorder and of precipitating and aggravating factors, such as repetitive activities that irritate the involved structures or prolonged, static strain. Avoidance of these factors may include modification of the work environment. For many soft tissue conditions, it should also be explained that the process of recovery may be lengthy. Relief of pain is another important principle. In addition to pharmacotherapy, TENS may be helpful in the management of local pain. Lack of exercise and improper use of muscles or poor posture often contribute to the development or persistence of soft tissue conditions. Rehabilitation therefore includes exercises in most soft tissue conditions, preferably designed and supervised by a physical therapist. An exercise programme should in general consist of graded flexibility and muscle conditioning exercises, as well as cardiorespiratory exercises. Evidence for the effectiveness of electrophysical treatment modalities other than TENS, such as low level laser therapy, ultrasound and thermotherapy, is scarce. Low level laser therapy and ice may be effective in lateral epicondylitis. Cryotherapy can also be applied in Achilles tendinopathies. Depending on the nature and site of involvement, various adaptive devices and orthoses, aiming to reduce strain or excessive movement, can be prescribed, such as heel raises in Achilles tendinopathy and wrist splints in carpal tunnel syndrome.

3.5 Low back pain

Low back pain is a common condition, with the majority of adults having low back pain at some time in their lives.. Most patients have ‘non-specific low back pain’ with, in general, a favourable prognosis. A minority of these patients will develop chronic low back pain, with symptoms persisting beyond 3 months. This group may be seen by the rheumatologist for treatment and/or to exclude low back pain resulting from inflammatory rheumatic conditions, in particular spondyloarthropathies.

With respect to rehabilitation in chronic low back pain (van Middelkoop et al 2011*), all patients should be instructed in self-care techniques. Any advice should stress the importance of maintaining activity as tolerated, with bed rest found not to improve either function or pain. Self-care education books based on evidence based guidelines are an efficient method to support the verbal information and advice provided by the clinician. There is no compelling evidence that lumbar supports are effective in patients with chronic low back pain. Home-based and supervised exercise programmes including muscle strengthening, spinal mobility, cardiorespiratory and mind-body exercises are effective and safe in patients with chronic low back pain. Back schools consist of an education and skills programme, including exercise therapy. Overall, the evidence for their effectiveness is inconsistent; they seem effective in an occupational but not in a primary healthcare setting. Referral to an interdisciplinary rehabilitation programme can be considered for patients with severe limitations of daily activities and societal participation (in particular paid work), in whom monodisciplinary treatment has failed.

Overall, there are no trials evaluating the optimal sequencing of non-pharmacological and non-surgical therapies, and there is no evidence to support the superiority of provision of care by specific clinicians. In general, clinicians should avoid prescribing interventions not proven to be effective. Factors to consider in advising a treatment regimen include cost, convenience, availability of skilled providers, and patient preference.

SUMMARY POINTS

- Rheumatology rehabilitation aims to enable people with rheumatic conditions to achieve and maintain optimal functioning in their lives.
- Rehabilitation interventions are a core part of the management programme for most rheumatic patients, as they contribute to the reduction of pain and maintenance of function and social interaction, with a decisive impact upon quality of life.
- Exercises and education are the cornerstones of rehabilitation in rheumatic conditions. In addition, aids and devices and orthoses and, to a lesser extent, (electro)physical treatment modalities may play a role in the rehabilitative management of rheumatic conditions.
- Complex multidisciplinary rehabilitation programmes require a high degree of patient involvement, and a structured plan for goal setting and rehabilitation.
- The rheumatologist can safely use and prescribe a variety of rehabilitation modalities to his or her patient's benefit, with emphasis on education and other self-management dimensions, exercise, activity pacing, common orthoses, and footwear.
- The rheumatologist is an important ally of the patient in finding the most appropriate rehabilitation resources and evaluating their efficacy.

IN-DEPTH DISCUSSION I

Fibromyalgia

Fibromyalgia is defined by subjective symptoms with widespread pain as its central feature. Widespread pain is typically accompanied by several other symptoms, with emphasis on fatigue and unrefreshed waking. Fibromyalgia is currently attributed to a derangement of central pain modulation: patients have lowered mechanical and thermal pain thresholds, high pain ratings for noxious stimuli, altered temporal summation of pain stimuli and ineffective inhibitory descending pathways. [Goldenberg et al, 2004].

Assessment of starting points for rehabilitation

Full understanding of fibromyalgia requires a comprehensive assessment of pain, physical functioning, emotional and social functioning, pain cognitions and maladaptive pain behaviour [Carville et al, 2008]. The health consequences for the individual diagnosed with fibromyalgia may vary from tolerable nuisance caused by pain interfering with daily activities to severely limited activities and restrictions in participation due to the multiple symptoms associated with this condition. The goal of all rehabilitation interventions for patients with fibromyalgia should be to reduce the activity- and participation restrictions caused by symptoms such as pain and fatigue.

Initial assessment should include a thorough understanding of the patient's resources and barriers in all domains in the ICF, including body function-/structure, activity and participation. Patients should be asked about their goals for improvement, beliefs and behaviour with respect to the symptoms, possible barriers and obstacles towards recovery and increasing activity levels [Goldenberg et al, 2004]. Illness perceptions and beliefs might be of particular importance, though evidence is still lacking. For instance, beliefs that rest is the best therapy that physical activities increase pain and that pain is harmful are common among patients with fibromyalgia, thus inducing physical inactivity.

Non-pharmacological treatment

Two important starting points of treatment are the acknowledgment of patient's symptoms by the rheumatologist and the patient's motivation to actively participate in treatment. Education with reassurance regarding "no harm" caused by physical activity should be the focal point of treatment [Fitzcharles et al, 2012]. Confirming the diagnosis and describing its clinical picture [Table 1] can have a positive impact on patients with fibromyalgia, in particular giving them validation and reassurance [Arnold et al, 2012]. Optimal treatment of fibromyalgia requires a combination of pharmacological and non-pharmacological treatment modalities. Core elements of non-pharmacological treatment of fibromyalgia are education, exercise therapy and cognitive behavioural therapy (Nuesch et al 2013, Bernardy et al 2013, Häuser et al 2010). Treatment should be tailored to individual needs.

A stepped care approach may be a valuable tool to guide non-pharmacological management of fibromyalgia [Goldenberg et al, 2004], implying that simple measures and interventions such as education should be tried

initially and offered to all patients, while interventions in later steps are reserved for those whose condition was not controlled by lower step treatment options. If education is not sufficiently effective, patients may be referred to an exercise program utilizing a graded approach in case of physical inactivity or to a cognitive behavioural treatment delivered by a psychologist if maladaptive cognitions and pain behaviour are pronounced. For patients with persistent complaints or suffering with a relatively high level of psychological distress a multimodal approach combining exercise with cognitive behavioural therapy is warranted [Häuser et al, 2008; Van Koulil et al, 2010]. In general, prescription for assistive devices and adaptation of the physical environment is not recommended, as these might uphold undesirable pain behaviour and increase physical inactivity. Evidence about the effectiveness of dietary interventions and complementary therapies, including acupuncture and homeopathic remedies is inconclusive, but these may be of benefit to individual patients.

Education

Education may be provided on an individual basis by a rheumatologist or a specialized nurse for patients with limited complaints. Patients should be informed about the benign nature of the disease and the beneficial effects of activity pacing, physical activity and sleep hygiene. Patients should be encouraged to find the optimal balance between different types of exertion and rest periods and to establish consistent patterns of alternating periods of rest and relaxation with periods of activity. Sleep hygiene measures include, amongst others, a fixed routine of getting to bed and rising, a daily exposure to daylight and the avoidance of reading and watching television in bed. For patients with a wide range of complaints interfering with multiple domains of daily functioning, referral to a specialised nurse or, if available, an educational group is warranted. A structured educational program has beneficial effects on pain, sleep, fatigue and quality of life [Goldenberg et al, 2004].

Educational programmes should be tailored to individual informational needs. Beliefs and misunderstandings about the aetiology and the chronicity of pain should be explored and discussed. Pain education focuses on explaining basic pain physiology and the contrast between acute versus benign chronic pain. “Pain depends on where your brain thinks a problem is, not necessarily where it really is” and “Acceptance that chronic pain cannot be cured reduces its impact” could be useful key concepts to explain. Components of educational programmes should also include strategies to cope with symptoms such as fatigue, pain or sleep disturbances. To accomplish sustained behavioural changes the use of techniques enhancing a patient’s motivation, such as motivational interviewing, is advocated. Education is a continuous process and can be integrated with exercise and/or cognitive behavioural therapy.

Exercise

Aerobic exercise reduces pain, fatigue and depressed mood, and improves health related quality of life and physical fitness, at post treatment. Any type and intensity of aerobic exercise such as (brisk) walking, biking or swimming is suitable, if tailored to patient's preferences regarding physical activities. [Häuser et al, 2010]

Patients should be advised that exercise is not harmful; it does not cause any damage to the body. However, it should be noted that exercise might temporarily increase pain after each exercise session at the start of the programme. In contrast to healthy people, patients with fibromyalgia might experience a reduced threshold for pain immediately after exercise [Nijs et al, 2012]. As a result, the early stages of exercise therapy programmes are typically prone to dropouts. Therefore, a graded-activity approach is generally advocated [Häuser et al, 2010]. Graded activity is directed at increasing exercise tolerance by increasing the level of activities in a time-contingent way; that is, the gradual increase of intensity of exercises is not symptom-driven but time-scheduled following a pre-set scheme. The ultimate goal of graded exercise is to integrate these activities in the daily living of patients to ensure long-term compliance. Goals and the gradual increase of physical activities are determined and agreed upon for every individual patient. Because the experience of pain is assumed to lead to limited progress, the intensity of exercise and activities at the start of the treatment period is set below the patient's usual activity level, making it likely that the patient can complete the activities successfully.

Picture 1 Patients with fibromyalgia should be advised that exercise is not harmful, but a graded activity approach is advocated (Photo: National Advisory Unit on Rehabilitation in Rheumatology)

Continuation of exercise is necessary to maintain positive effects on pain [Nijs et al, 2012]. Therefore, education on strategies to integrate physical activity in daily life should be given. In addition, mind-body interventions such as relaxation exercises and Tai Chi exercises [Wang et al, 2010] to improve awareness and reduction of muscle tension may complement aerobic exercise.

Cognitive behavioural therapy (CBT)

Cognitive behavioural therapy is built upon the assumption that cognitions influence emotions and behaviour and vice versa. CBT aims to solve problems concerning dysfunctional emotions, behaviours and cognitions through a goal-oriented, systematic procedure. Cognitive behavioural therapy should be provided by skilled health professionals such as psychologists or health professionals with CBT education.

Several randomised clinical trials have explored the usefulness of cognitive behavioural therapy for managing fibromyalgia [Nuesch et al, 2013]. CBT interventions typically include three elements: (1) an educational phase—in which patients are familiarized with a model for understanding their pain, (2) a skills training phase—in which training is provided in a variety of cognitive and behavioural pain-coping skills (e.g. cognitive restructuring techniques, activity pacing, pleasant activity scheduling, problem-solving, sleep hygiene), and (3) an application phase—in which patients learn to apply their skills in progressively more challenging real-life situations [Williams et al, 2003]. Real-life situations include work, leisure and social relationships. CBT has shown small incremental benefits over control interventions in reducing pain, negative mood and disability at the end of treatment and at long-term follow-up [Bernardy et al, 2013]

IN-DEPTH DISCUSSION II

Footwear in rheumatic diseases

This in-depth discussion will address two different instances where the rheumatologist should take a professional interest in footwear:

1. Foot problems in rheumatic diseases, which can be ameliorated by appropriate footwear
2. The use of footwear to improve rheumatic conditions in anatomical regions other than the feet.

MANAGEMENT OF FOOT PROBLEMS IN RHEUMATIC DISEASES

Foot problems in rheumatic diseases

Foot involvement is common in a number of rheumatic diseases and tends to have a considerable impact upon patients' quality of life, due to direct interference with mobility and societal participation.

Approximately 80-90% of individuals with rheumatoid arthritis (RA) are reported to have symptoms in the feet [Grondal et al, 2008]. The most frequent foot problems in RA include pain on the soles of the feet, particularly in the metatarsal areas. This may be due to a number of reasons. In the early phases of the disease it is most usually be due to synovitis of the metatarsophalangeal (MTP) joints. In later phases, dorsal subluxation of the proximal phalanges with anterior displacement of the fat pad, together with collapse of the transverse arch of the forefoot may lead to bursitis, callosities and skin breakdown, causing pain and difficulty in walking. Hallux valgus and cock-up deformities or claw toes of the lesser rays associated with plantar plate and structural joint damage may produce pressure against the shoe (Figure 1). In the hindfoot and midfoot, a complex deformity observed in advanced RA or psoriatic arthritis seems to start with subluxation of the talo-navicular joint, which causes a flattened medial arch with subsequent pronated midfoot and lateral deviation of the forefoot. In extreme cases the foot comes to rest medially, on the subluxed the talonavicular joint (Figure 2), with pain as an inevitable consequence. Another common deformity in late stages of the disease is hind foot valgus due to subtalar joint involvement (Figure 3). Apart from complaints associated with deformities, patients with RA may have foot problems related to the skin (ulceration), nails (infection), vascular (vasculitis) and/or neurological symptoms (sensory loss), which may also contribute to limitations of foot function and gait [Williams et al, 2011].

The most common site of involvement in the osteoarthritic foot is the first MTP joint. Examination reveals restricted mobility of the joint, particularly in extension (hallux rigidus). A hallux valgus with bunion formation is also frequently seen in OA. There has been increasing interest in osteoarthritis of the midfoot, which has been shown recently to be far more common than thought previously, and is linked to trauma, inflammatory arthropathy, mechanical stress and idiopathic osteoarthritis [Roddy et al 2013].

Figure 1

Figure 2

Figure 3

In ankylosing spondylitis, two common sites for enthesitis are under the heel where the plantar fascia attaches and behind the heel at the Achilles tendon insertion [Clark, 1996].

Hallux valgus, flat feet, pes cavus and plantar fasciitis can present in connection with rheumatic conditions or as independent disorders.

Management of the rheumatic foot

Any foot management strategy starts with an appropriate assessment [Williams et al, 2011; Clark, 1996; Helliwell et al, 2011; Helliwell, 2003; Rao et al, 2012], which should take not more than 1 minute [Helliwell et al, 2011]. History taking should include an evaluation of the rheumatic condition and general health, foot symptoms, activities of daily living and lifestyle [Williams et al, 2011]. The physical examination starts with a simple, but systematic observation of the overall foot shape and palpation of the relevant joint margins, soft tissue structures and insertions, to identify inflamed or damaged tissues and a careful inspection of the skin and nails. Next, active movement of the foot is evaluated, assessing the direction, range and quality of motion and any related pain. In addition, clinician mediated passive motions of ankle, subtalar, midfoot and forefoot joints, noting pain and again the direction, range and quality of movement and gait are performed [Williams et al, 2011; Helliwell et al, 2011]. The assessment is completed with an inspection of the patient's footwear. Foot-specific questionnaires can also be used to quantify the severity of pain and functional disability [Rao et al, 2012].

When considering adaptations of footwear or appliances for the rheumatic foot it is important to consider the potential mechanisms through which they can help:

- relieve excessive pressure
- reduce shock and shear
- accommodate, correct or support deformities
- control or limit painful motion of joints [Clark, 1996].

Table 1 summarizes the possible functions of special shoes and foot orthoses. Table 2 gives examples of common rheumatic foot problems and possible solutions [Beardmore, 2001].

The effects of adapted footwear, insoles and inlays in rheumatic diseases have been assessed in several systematic reviews [Riskowski et al, 2011; Hennessy et al, 2012; Clark et al, 2006; Hawke et al, 2008], which included, however, a limited number of high quality randomized controlled trials.

For most patients, the use of “off-the-shelf” or stock footwear will be sufficient to suit their needs, whereas a limited number of patients are in need of custom-made or bespoke shoes. Patients may benefit with advice regarding the selection of shoes from very early on in their disease course, even before deformity makes the need obvious.

Generally desirable features of shoes for patients with rheumatic conditions are:

- a deep and wide toe box to accommodate toes that are flexed up,
- sufficient width to accommodate the splayed forefoot,
- sufficient plantar support, in particular a supportive medial arch,
- thick, soft sole with the ability to absorb and distribute pressures (e.g. by means of air or synthetic foams) and
- non-raised and broad-based heel, maximum height 2-3 cm,
- the shoe should be laced or otherwise fastened securely on the foot and has enough room to place devices in it,
- the shoes should be comfortable and keep dry inside.

Table 1. Function of special shoes and foot orthoses

1. To accommodate deformities and relieve pressure
2. To support the biomechanical mal-alignment and reduce associated abnormal compensatory movements.
3. To provide cushioning and shock absorption.
4. To redistribute weight bearing to a more normal pattern throughout the gait circle.
5. To support the hindfoot and the longitudinal arch in order to reduce excessive pronation.
6. To support the transverse arch and provide lift to the metatarsophalangeal joints, reducing weight bearing on these joints.
7. To decrease excessive and/or aggravating articular movement during weight bearing.

Adapted from: Clark BM. Foot management and ambulatory aids. In: Wegener ST, Belza BL, Gall EP (eds). Clinical care in the rheumatic diseases. American College of Rheumatology, Atlanta, 1996.

Table 2. Shoe specifics for common rheumatic foot problems

Condition	Clinical Problem	Solution
RA / OA	Hallux valgus with bunion	Wide, soft, deep toe box, stretch medial leather
RA	Cock-up toes	Deep toebox, soft leather upper, stretch upper, donut pads, sandals
RA	Valgus hindfoot	Medial wedge/medial arch support, lace-up canvas ankle support, ankle-hindfoot orthosis
RA	MTP subluxation with callosities	Metatarsal bar, metatarsal pad or sole inserts aiming to redistribute pressure under the foot and/or limit intersegmental motion
OA	Hallux rigidus	Metatarsal bar, rigid sole, rocker-bottom sole to limit stress and motion through the first metatarsophalangeal joint
AS	Heel pain	Rubber or plastic heel cups, sponge inserts with a hole cut

Adapted from: Beardmore T. Rehabilitation. In: Klippel JH, Crofford LJ, Stone JH, Weyand CM (eds). Primer on the rheumatic diseases. 12th edition. Arthritis Foundation, Atlanta, Georgia, 2001.

Please note that commonly available sports shoes, walking shoes or off-the-shelf shoes for people with foot problems are frequently enough to fulfil these requirements (Figure 4). Sometimes individually-tailored shoe modifications are necessary.

In RA, extra-depth shoes or insoles can, in general, be expected to offer benefit upon pain and functional ability. External shoe modifications may consist of rocker soles, extended steel shanks, stabilizers, wedges or extensions. A toe rocker-soled shoe is thought to reduce pain by decreasing forefoot loading and promoting a normal heel-toe motion during gait (Figure 5). With disease progression, patients with RA move from a heel-toe rolling gait to a more shuffled step with a delayed heel lift and the toe rocker-soled shoe may slow this progression [Riskowski et al, 2011].

Figure 4

Figure 5

Insoles may be designed to provide cushioning and shock absorption, to relieve pressure and redistribute weight bearing and to relieve pain and swelling. Insoles can either be commercially available devices or may be custom made. They may be made of soft, compressible material, or more rigid material, requiring the making of a cast of the foot first (Figure 6). Metatarsalgia and medial arch collapse are the most common indications for insoles in patients with RA. There is some evidence that rigid orthoses used in fairly early disease slow progression of deformity, reduce pain and functional limitation [Woodburn, 2002]. Overall, the recommendation is that foot orthotics should be custom-designed to meet the individual's unique needs to reduce pain [Hennessy et al, 2012].

Callus over the plantar metatarsal area should be removed with caution, as it may have a protective role [Williams et al, 2011]. If a debridement is considered, pressure-relieving insoles should be provided in order to protect the foot from the risk of ulceration [Williams et al, 2011]. The effect of debridement is although not clear [Siddle et al, 2013].

The hindfoot valgus deformity in RA with pronation in the midfoot needs special attention. As long as this deformity is correctable, patients may have some benefit from a medial arch support [Woodburn, 2002]. However, when there is a fixed valgus deformity of the hindfoot, which is the case in most RA patients, such a device is not able to correct the deformity, and will increase the risk of pressure sores of the skin under the medial arch.

Apart from insoles, patients may benefit from small inserts such as foam rubber spacers and doughnut hole pads, dealing with overlapping toes and pressure points. Custom made shoes are needed in case of severe foot deformities (Figure 7). As “ready-made” orthopaedic shoes will most likely not meet individual requirements, they should not be advised in these cases.

Figure 6

Figure 7

FOOTWEAR FOR RHEUMATIC CONDITIONS IN OTHER ANATOMICAL SITES THAN THE FEET

Overall, the literature suggests that in patients with knee OA, footwear can affect knee joint loads, whereas in hip OA the evidence is scanty [8]. Nevertheless, based on expert opinion, it is recommended that, in both hip and knee OA, clinicians should evaluate the patient's feet and shoes when exploring treatment strategies. In general, patients with hip and knee OA should be advised to wear shoes with thick but soft soles, and minimally raised heels. In patients with medial tibiofemoral knee OA with varus deformity, full-length lateral wedged insoles could be considered [Brouwer et al; 2005] although many patients do not tolerate valgus

wedges well. In patients with lateral tibiofemoral OA with valgus deformity or patients with RA and knee involvement, where valgus deformity is more common than varus deformity, medial wedged insoles can be recommended.

Shoe lifts by means of an internal or external pad (or both) may be used to correct leg length discrepancy, especially if this has developed later in life, e.g. after surgery or a fracture. In adults, minor length discrepancy (asymmetries between 0.75 and 2.50 cm) can be corrected, with a generally accepted extent of 50% of the discrepancy. Shoe lifts are inexpensive and can be removed if they are not effective.

PRESCRIBING FOOTWEAR

Patients with rheumatic conditions and foot problems or other symptoms which could benefit from appropriate footwear should be referred to a podiatrist or orthopaedic shoemaker in an appliance department where stock or bespoke footwear with insoles are provided. Specialist rheumatology podiatry and multidisciplinary approaches to foot problems are only available in a limited number of places [Helliwell, 2003]. From the literature it is known that much therapeutic footwear will end up as “shoes in the cupboard” [Brouwer et al, 2005; de Boer et al, 2009]. Reasons for not using orthopaedic footwear include a negative evaluation (ease of use, dislike of appearance, not fitting well and lack of comfort) [De Boer et al, 2009] or a lesser need [Van der Esch et al, 2003]. Specialist therapeutic footwear impacts more on the patients’ body image and emotions than previously acknowledged [Williams et al, 2007a]. Therefore, patients must be effectively engaged and empowered in the choice of footwear as an acceptable intervention for their foot problems [Williams et al, 2007b]. To ensure that the patient is satisfied with the result of the intervention, multiple visits may be necessary.

Glucocorticoids

Lisa Ehlers, Cindy Strehl, Rene Westhovens

Previous versions were co-authored by Frank Buttgereit, Cornelia Spies, John Kirwan, Johannes Jacobs, Marlies van der Goes, Barbara Neerinckx, Rene Westhovens

LEARNING OBJECTIVES

- ➔ Describe the pharmacologic characteristics of glucocorticoids
- ➔ Explain the different mechanisms of glucocorticoid actions
- ➔ Evaluate the therapeutic effects of glucocorticoids
- ➔ Clarify the appropriate terminology for glucocorticoid treatment
- ➔ Give examples of treatment regimens for specific clinical situations
- ➔ Describe the adverse effects of glucocorticoid therapy
- ➔ Evaluate the need for protective measures and monitoring
- ➔ Outline approaches to the development of new glucocorticoids

1 Introduction

Glucocorticoids have become the most important and frequently used class of anti-inflammatory drugs since their introduction into clinical practice in 1948. The estimated prevalence of the use of glucocorticoids in the general adult population ranges from 0.5–1.2% (Overman et al, 2013). The 1.2% prevalence is an estimate from the USA, corresponding to 2,513,259 individuals, mostly chronic glucocorticoid users, with a non-significant downward trend of glucocorticoid use from 1999 to 2008 (Overman et al, 2013). For patients with rheumatoid arthritis (RA), worldwide estimates of the percentages on treatment with glucocorticoids range from 15% to 90% (Sokka et al, 2009). Glucocorticoids are relatively inexpensive drugs, but due to the great volume prescribed, the total financial market size is huge.

The major reasons for the widespread use of these drugs are—next to low cost—their versatility and effectiveness, although, especially if applied at higher dosages and/or for longer treatment durations, glucocorticoids have a wide range of adverse effects (figure 1).

Figure 1 Broad spectrum of effects of glucocorticoids. CNS, central nervous system; DMARD, disease-modifying antirheumatic drug; HPA, hypothalamic–pituitary–adrenal; NSAIDs, non-steroidal anti-inflammatory drugs; RA, rheumatoid arthritis. (Reproduced with permission from Hoes et al. *Nat Rev Rheumatol* 2010;6:693–702.)

There have been important developments in the past decades. Joint sparing capacities of glucocorticoids in early RA have been recognised. The increased understanding of basic inflammatory mechanisms provides a basis for the development of new drugs. New applications have been introduced and international guidelines on therapy and management have been created, enabling safer use of these drugs. In this chapter, we focus on the characteristics of glucocorticoids and the therapeutic effects and adverse effects which are frequently seen in clinical practice.

2 Characteristics of glucocorticoids

2.1 Structure

Cholesterol is the precursor of all steroid hormones, such as sex hormones, mineralocorticoids and glucocorticoids. The term 'steroid' refers to the basic sterol skeleton. Sex hormones are predominantly produced in the gonads, but also in the adrenal cortex. Mineralocorticoids, of which aldosterone is the main natural hormone are synthesised in the adrenocortical zona glomerulosa. Cortisol (hydrocortisone), the major endogenous glucocorticoid is produced in the adrenocortical zona fasciculata.

2.2 Classifications

Classification of steroids into mineralocorticoids and glucocorticoids is not completely accurate, because the groups slightly overlap (eg, endogenous glucocorticoids also have some mineralocorticoid effects). However, synthetic (exogenous) glucocorticoid drugs are more restricted to glucocorticoid effects only; therefore it is considered appropriate to use the term 'glucocorticoids' when referring to glucocorticoid drugs (Buttgereit et al, 2002*).

Glucocorticoids can also be classed according the duration of their effect or their solubility in water and other characteristics (table 1). Even though experimental and clinical evidence for the preciseness of their relative potencies is weak, and although at high and very high dosages non-genomic effects also occur which may change the relative potencies of the different glucocorticoids, these estimated potencies are useful in daily clinical practice as a general therapeutic guideline.

Imprecise semi-quantitative textual labelling of glucocorticoid doses warranted a standardised dose classification (table 2) (Buttgereit et al, 2002*); it is based on the extent of cytosolic glucocorticoid receptor (GR) occupation of glucocorticoids and genomic and non-genomic effects at different dosages. Precise description of glucocorticoid therapy should not only include the dosage and type of drug, but also the route of administration, the timing of administration during the day, the proposed duration of the therapy, and the cumulative dosage, where appropriate.

Table 1: Classification according pharmacodynamics of glucocorticoids used in rheumatology

	Equivalent glucocorticoid dose (mg)	Relative glucocorticoid activity	Relative mineralocorticoid activity ¹	Protein binding ²	Half-life (hr) in plasma	Biological half-life (hr)
<i>Short-acting</i>						
Cortisone	25	0.8	0.8	-	0.5	8-12
Cortisol	20	1	1	+++	1.5 - 2	8-12
<i>Intermediate-acting</i>						
Methylprednisolone	4	5	0.5	-	> 3.5	18-36
Prednisolone	5	4	0.6	+	2.1 - 3.5	18-36
Prednisone	5	4	0.6	++	3.4-3.8	18-36
Triamcinolone	4	5	0	+	2 - >5	18-36
<i>Long-acting</i>						
Dexamethasone	0.75	20-30	0	+	3 - 4.5	36-54
Betamethasone	0.6	20-30	0	+	3 - 5	36-54

¹ clinical signs: sodium and water retention, potassium depletion

² symbols: -= none; += high; ++= high to very high; +++= very high

Table 2: Classification of glucocorticoid dosages

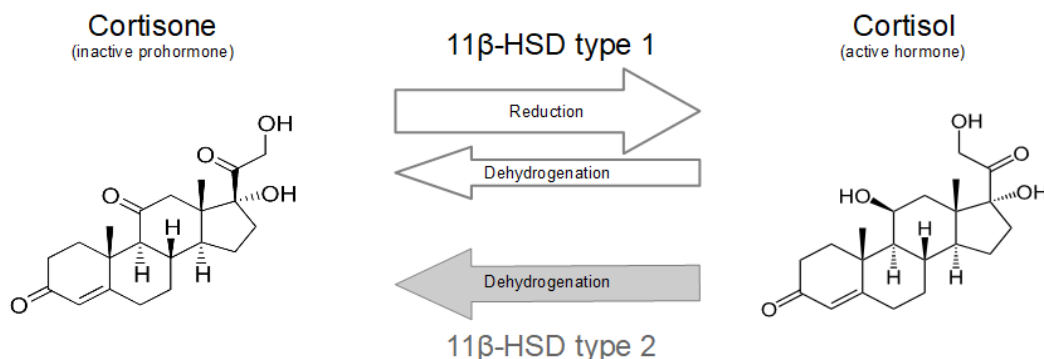

Low dose	≤ 7.5 mg prednisone equivalent per day
Medium dose	> 7.5 mg and ≤ 30 mg prednisone equivalent per day
High dose	> 30 mg and ≤ 100 mg prednisone equivalent per day
Very high dose	> 100 mg prednisone equivalent per day
Pulse therapy	≥ 250 mg prednisone equivalent per day for one or a few days

2.3 Conversion into active hormones and vice versa

Cortisone and prednisone are inactive prohormones. They are chemically reduced in the liver into their active forms cortisol and prednisolone, which have high affinity for the GR. This generation of biologically active glucocorticoids from their inactive forms is promoted by the reductase action of the intracellular enzyme 11 β -hydroxysteroid dehydrogenase (11 β -HSD) type 1.

The same enzyme can, by dehydrogenation, also promote the reverse reaction, leading to inactivation of active glucocorticoids. In contrast, 11 β -HSD type 2 has dehydrogenase activity only, so it only catalyses the conversion of active glucocorticoids to their inactive forms (Box 1).

Box 1 Reduction of the inactive prohormone cortisone to the active hormone cortisol by the enzyme 11 β -HSD type 1. An inactivation of cortisol is catalysed by the dehydrogenase activity of 11 β -HSD type 1 and type 2.

In different tissues, local balance between the intracellular enzymes 11 β -HSD type 1 and type 2 might modulate intracellular glucocorticoid concentrations and thus tissue sensitivity for glucocorticoids (Buttgereit et al, 2008b). Synovial tissue metabolises glucocorticoids via the two 11 β -HSD enzymes, with the net effect being glucocorticoid activation; this increases with inflammation. This endogenous glucocorticoid activation in the joint is likely to have an impact on local inflammation and on bone of the joint (Hardy et al, 2008).

In the case of serious liver insufficiency this conversion is less efficient, and the active glucocorticoids should be prescribed instead of the prohormones.

2.4 Water and lipid solubility

Glucocorticoids in free form (as alcohol) are insoluble in water and can be used in tablets. Absorption occurs presumably within 30 min and the bioavailability of prednisone and prednisolone is high. Glucocorticoid esters also have limited water solubility but are lipid soluble and therefore are suitable for intramuscular, intralesional and intra-articular use. Glucocorticoid salts are water soluble and thus can also be administered intravenously. For local (intra-articular or intralesional) treatment, less water soluble preparations are to be preferred, since the less water soluble they are, the longer the duration of the effect.

2.5 Protein binding

Only 5–10% of the natural glucocorticoids circulate in free form and are biologically active. The remaining are bound to proteins, primarily transcortin (also called glucocorticoid-binding globulin) and albumin. The half-life is dependent on protein binding, distribution to different body compartments which also depends on protein binding, affinity for the cytosolic GR (which is higher in synthetic glucocorticoids), and the rate of metabolism. Patients with low levels of plasma proteins, which can be caused by liver diseases or chronic active

inflammatory diseases, are therefore more susceptible to effects and adverse effects, and dose reduction should be considered.

2.6 Metabolism and drug interactions

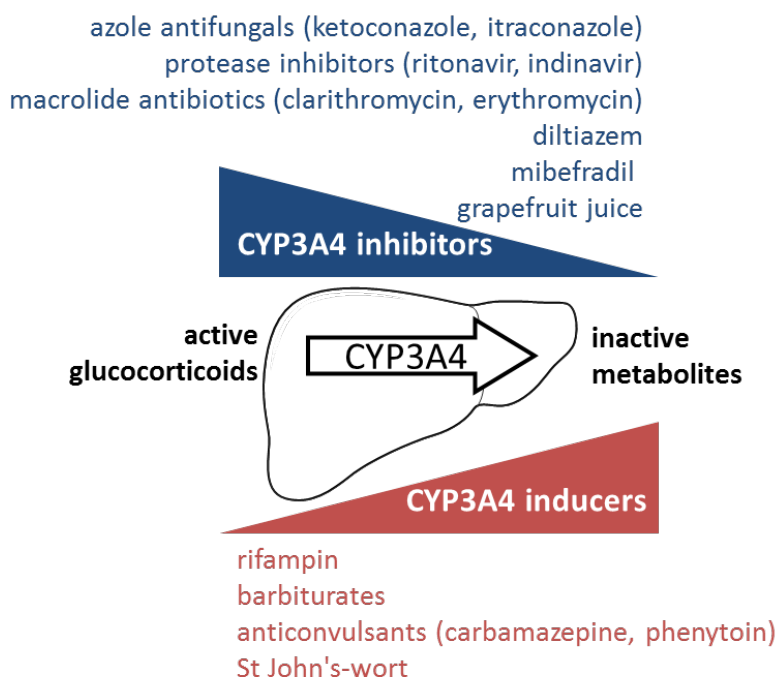

Pharmacologically active glucocorticoids are metabolised by isozymes of the cytochrome P450 (CYP) in the liver into inactive metabolites, which are excreted in the urine. As a consequence, patients with renal or liver disease may have increased half-lives of active glucocorticoids, resulting in increased effects at a given dose, but in general patients with renal insufficiency do not require dosage adjustment. Prednisolone is partially removed by haemodialysis.

Drug interactions are based on induction or inhibition of CYP enzymes. CYP3A4 inducers like rifampin increase the breakdown of glucocorticoids, diminishing their effects to a clinically relevant extent (Schulte et al, 1987). . On the other hand, concomitant therapy with inhibitors of CYP3A4 might result in an increased risk of (adverse) effects (Varis et al, 2000a; Varis et al, 2000b) (Figure 2). To complicate matters, ketoconazole in doses of 400–800 mg per day inhibits the synthesis of cortisol induced by adrenocorticotrophic hormone (ACTH) and is used to treat Cushing disease (the pituitary-dependent cause of Cushing syndrome). However, several CYP3A4 inhibitors are probably not that important for prednisone and prednisolone metabolism; also the effect of grapefruit juice intake is likely to be of limited clinical significance (Varis et al, 2000c).

Concomitant therapy with prednisolone and cyclosporine may result in higher plasma prednisolone concentrations, whereas concomitant therapy with methylprednisolone and cyclosporine may result in increased cyclosporine concentrations. This is probably caused by competitive inhibition of microsomal liver enzymes. Sulphasalazine has been reported to increase the sensitivity of immune cells for glucocorticoids (Oerlemans et al, 2007), which could be beneficial, but the clinical relevance of this finding has yet to be confirmed.

2.7 Sensitivity and resistance to glucocorticoids

The several potential mechanisms involved in the variability of glucocorticoid sensitivity have not all been fully elucidated (Barnes and Adcock, 2009). Modulation of these mechanisms could potentially reduce the proportion of patients who fail or react less favourably as expected on these drugs. Also, more research on hereditary glucocorticoid resistance (rare) and the antagonising actions of cytokines is warranted.

Figure 2 Drug interactions based on induction and inhibition of CYP3A4

Summary : The major endogenous glucocorticoid cortisol is produced in the adrenocortical zona fasciculata from the steroid precursor cholesterol. Two different types of the enzyme 11 β -hydroxysteroid dehydrogenase (11 β -HSD) are responsible for the inactivation of cortisol to cortisone and/or vice versa. Pharmacologically glucocorticoids are classified based on their duration of action. Other relevant pharmacodynamic features are mineralocorticoid activity, protein binding, half-life and solubility. Drug inactivation by members of the cytochrome P450 superfamily takes place in the liver.

3 Basic mechanisms of glucocorticoids

Glucocorticoids influence the transcription of about 1% of the entire genome. This results in a very broad spectrum of effects induced by a single class of endogenous hormones and hormonal drugs.

3.1 Genomic and non-genomic mechanisms

Effects of glucocorticoids are mediated via classic genomic mechanisms and via non-genomic mechanisms.

3.1.1 Genomic mechanisms

Anti-inflammatory and immunomodulatory effects of glucocorticoids are predominantly based on genomic mechanisms (Buttgereit et al, 2004) (figure 2). Unbound glucocorticoid molecules can cross the cell membrane, because of their lipophilic structure and low molecular weight. They bind to the α isoform of cytosolic GCRs, which is present in almost all tissues; the β isoform is not capable of binding to glucocorticoids.

The cytosolic GCR is a multiprotein complex with several heat shock proteins attached as chaperones, which are shed after binding of the glucocorticoid. A receptor–glucocorticoid complex is formed and rapidly translocated into the nucleus. In the nucleus, this GCR–glucocorticoid complex can influence gene expression via binding as a dimer to specific consensus sites in the DNA, resulting in induction of regulatory protein synthesis. This effect is called transactivation. GCR–glucocorticoid complexes as monomers also interact with transcriptional factors (such as activator protein-1, interferon regulatory factor-3 and nuclear factor kappa B), leading to inhibition of binding of these transcriptional factors to their consensus sites in the DNA. This process results in down-regulation of predominantly pro-inflammatory protein synthesis and is called transrepression.

Figure 3 Genomic actions of glucocorticoids. *Glucocorticoid binds to the glucocorticoid receptor (GR) in the cytoplasm. This complex migrates into the nucleus. Activation of transcription (transactivation) by binding of GR–glucocorticoid complex dimers to glucocorticoid-responsive elements of DNA up-regulates synthesis of regulatory proteins, thought to be responsible for metabolic effects and also some anti-inflammatory/immunosuppressive effects. Interaction of GR–glucocorticoid complex monomers with pro-inflammatory transcription factors, such as activator protein-1, interferon regulatory factor-3, and nuclear factor-kappa B (NF-κB) leads to inhibition of binding of these transcriptional factors to their DNA consensus sites (for NF-κB: NF-κB-responsive elements). Thus the transcription of these pro-inflammatory transcription factors is repressed. This is called ‘transrepression’ and down-regulates synthesis of predominantly inflammatory/immunosuppressive proteins. (Adapted from Jacobs JWG, Bijlsma JWI. Glucocorticoid therapy. In: Firestein CS, et al, eds. Kelley and Firestein’s textbook of rheumatology. 10th edn. Philadelphia: Saunders Elsevier, 2017:932–57.)*

Genomic mechanisms occur with all dosages of glucocorticoid therapy, even at very low ones. Genomic effects are relatively slow, and significant changes in regulatory proteins are seen after at least 30 min. Although between 10 and 100 genes per cell are directly regulated by glucocorticoids, many genes are regulated indirectly through interaction with transcription factors and co-activators. Therefore, it may take hours or up to days to realise maximal therapeutic effects.

Glucocorticoids also act through post-transcriptional and post-translational mechanisms. They decrease the stability of messenger RNA through the induction of ribonucleases. This mechanism could be an explanation for the inhibition by glucocorticoids of synthesis of interleukin (IL)-1, IL-6, granulocyte-macrophage colony-stimulating factor, and inducible cyclo-oxygenase (COX) (Ristimäki et al, 1996)—that is, COX-2.

It has been suggested that transrepression is responsible for several desirable anti-inflammatory and immunomodulating effects, whereas transactivation is associated with frequently occurring side effects as well as with some immunosuppressive activities. If this hypothesis is true, selective GR agonists (SEGRAs) exerting almost exclusively transrepression and no or very limited transactivation would show glucocorticoid therapeutic activity and fewer side effects. However, a study in a mouse strain with a deficiency to form dimer GR–glucocorticoid complexes, and thus with a transactivation deficiency, showed—along with a failure of glucocorticoids to exert a full anti-inflammatory response—classic side effects in these mice, such as osteoporosis (Vandevyver et al, 2013). Furthermore, in an asthma trial the effect of a SEGRA was disappointing (Bareille et al, 2013). Several clinical trials to investigate the efficacy and safety of different SEGRA formulations are ongoing or completed, but due to the lack of publications of the study results, clinical evidence is still missing.

3.1.2 Non-genomic mechanisms

Although clinically the effects of non-genomic mechanisms cannot be discriminated from effects of genomic mechanisms, effects of non-genomic mechanisms occur more rapidly, even within seconds or minutes. Today, non-genomic mechanisms are classified into 3 groups

- mechanisms caused by the release of proteins from the cytosolic GR multi-protein complex after GC binding
- interaction with membrane-bound GC receptors which are present on peripheral blood mononuclear cells (Buttgereit et al, 2011)
- non-specific GC effects resulting from the interaction of GC - especially at very high concentrations - with cellular membranes.

Most non-genomic mechanisms still need to be unravelled; hopefully this will yield therapeutic targets for development of new drugs.

Clinical evidence of the existence of non-genomic effects includes the spontaneous improvement of clinical symptoms after the application of high doses, immediate onset of action in the treatment of anaphylaxis and rapid effects following topical application (Buttgereit and Scheffold, 2002).

3.2 Immunosuppressive and immunomodulatory actions

Glucocorticoids reduce activation, proliferation, differentiation, and survival of different inflammatory cells, such as different types of leucocytes, endothelial cells and fibroblasts via manifold mechanisms (Coutinho and Chapman, 2011). This is the main glucocorticoid therapeutic action in most rheumatic diseases. In general, the higher the dose of glucocorticoids, the stronger the effect. Therefore, low doses can be effective in inhibiting signs and symptoms of joint inflammation in RA, but high doses and pulses of glucocorticoids are needed to treat life-threatening vasculitis or other very serious situations.

The absolute numbers of most inflammatory cell types in the body decrease with glucocorticoid administration. There are less circulating monocytes/macrophages and their synthesis of pro-inflammatory cytokines and prostaglandins as well as their expression of MHC class II molecules and Fc receptors are reduced. The number of circulating T-cells and their production and action of different cytokines (e.g. IL2) are diminished. The numbers of eosinophil and basophil granulocytes are reduced, whereas the number of circulating neutrophils is increased. This is the result of down-regulation of adhesion molecules by glucocorticoids, thereby preventing migration of neutrophil granulocytes from the circulation to inflammatory sites. The number of B cells and immunoglobulin production are hardly affected by glucocorticoid treatment, but the actions of glucocorticoids on B cells are not well understood (Baschant et al, 2012).

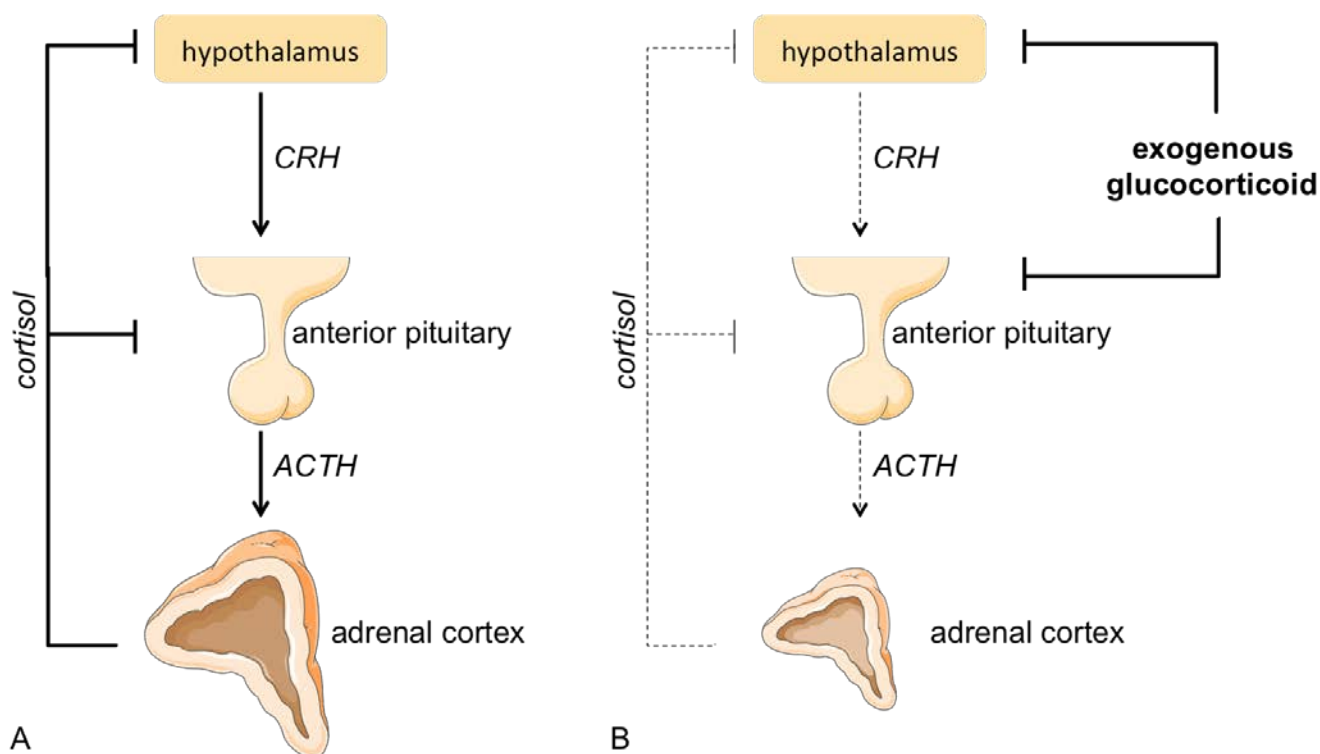

The effects of glucocorticoids on cytokine production and levels are complex. Especially in higher doses, glucocorticoids inhibit synthesis of most of the pro-inflammatory cytokines which play important roles in the development of synovitis, cartilage degradation and bone erosions, such as IL-1 β , IL-2, IL-3, IL-6, tumour necrosis factor α (TNF α), interferon- γ (a typical T helper (Th)1 cytokine), and IL-17 (a Th17 cytokine). Glucocorticoids stimulate or do not affect production of Th2 and regulatory cytokines such as IL-4 (a typical Th2 cytokine), IL-10 and IL-13, which are related to B cell activation and extra-articular features of RA. In macrophages, glucocorticoids at low concentrations enhance secretion of nitric oxide—via the cytokine-inducible form of nitric oxide synthase—and expression of pro-inflammatory cytokines, but glucocorticoids at high concentrations inhibit these (Lim et al, 2007). Glucocorticoids also inhibit the expression of adhesion molecules, such as intercellular adhesion molecule-1 and E-selectin, and chemotactic cytokines such as IL-8 and macrophage chemo-attractant proteins. Glucocorticoids inhibit COX-2 in arachidonic acid metabolism, decreasing levels of inflammatory prostaglandins and destructive proteinases.

3.3 Suppression of hypothalamic–pituitary–adrenal axis

Administration of glucocorticoids leads to negative feedback on the hypothalamus and pituitary glands, resulting in less secretion of corticotropin-releasing hormone (CRH) and ACTH, respectively. As a result, the cortisol secretory capacity of the fasciculate-reticularis zone of the adrenal cortex may decrease, since this inner cortical zone producing cortisol is dependent on ACTH for structure and function. Chronic suppressed

cortisol production leads to atrophy of the fasciculate-reticularis zone and clinically to adrenal insufficiency (figure 4), referred to as tertiary adrenal insufficiency, due to the inhibition of CRH release (Charmandari et al, 2014). When ending glucocorticoid therapy or in case acute stress or injury it is important to bear this in mind to prevent an adrenal crisis (also known as Addisonian crisis) (see also 5.8). The outer glomerulosa zone is not dependent on ACTH and therefore its ability to produce mineralocorticoids is not impaired, in contrast to when there is primary adrenal insufficiency, for example, by autoimmune adrenal damage (morbus Addison). However, hyponatraemia can be a symptom of tertiary adrenal insufficiency resulting from increased ADH release (Grammatiki et al, 2016).

Figure 4 *Suppression of the hypothalamic-pituitary-adrenocortical axis. In healthy individuals (A) CRH (corticotropin-releasing hormone) from the hypothalamus increases ACTH (adrenocorticotrophic hormone) secretion from the anterior pituitary gland, stimulating the adrenocortical fasciculate-reticularis zone. Cortisol is released and leads to a suppression of CRH and ACTH secretion by negative feedback. During therapy (B) the exogenous glucocorticoid has the same effect causing atrophy of the adrenocortical fasciculate-reticularis zone.*

Summary : Glucocorticoids mediate their strong anti-inflammatory and immunosuppressive effects via genomic and non-genomic mechanisms. Genomic mechanisms of glucocorticoid actions are mediated by the cytosolic glucocorticoid receptor resulting in an increased transcription of regulatory proteins (transactivation) and/or a suppressed transcription of pro-inflammatory proteins (transrepression). Non-genomic mechanisms are responsible for very rapid glucocorticoid effects. Glucocorticoids have a strong influence on most immune cells and thereby on the production of different cytokines. Glucocorticoid treatment leads to a suppression of the HPA axis causing a decreased cortisol secretion in consequence of adrenal atrophy. To prevent clinically manifest adrenal insufficiency, glucocorticoids have to be tapered carefully after chronic use and patients should be informed about possible complications.

4 Applications in rheumatology

Glucocorticoids have multiple therapeutic effects, ranging from pain relief and disease modifying results to strong immunosuppressive actions. Depending on the underlying disease and the desired therapeutic aim (table 3), the route, type of glucocorticoid, dose and duration of glucocorticoid therapy are chosen. These not only determine the magnitude of clinical effect and speed of action, but also the risk of developing adverse effects. Here we discuss the administration of glucocorticoid therapy, with emphasis on use in RA, because the therapeutic roles of glucocorticoids in the management of other rheumatic diseases will be discussed in more detail elsewhere.

Table 3: General use of glucocorticoids in rheumatology, initial doses*

	oral			intravenous
	low*	medium*	high*	very high dose/pulse
Arthritides				
gouty arthritis, acute	-	2	2	-
juvenile idiopathic arthritis	-	1	1	-
osteoarthritis	-	-	-	-
acute CPP crystal arthritis	-	-	-	-
psoriatic arthritis	-	1	-	-
reactive arthritis	-	-	-	-
rheumatic fever	-	1	1	-
rheumatoid arthritis	2	2	1	1
Collagen disorders				
dermatomyositis, polymyositis	-	-	3	1
mixed connective tissue disease	-	1	-	1
polymyalgia rheumatica	-	3	-	1
Sjögren's syndrome, primary	-	-	1	-
systemic lupus erythematosus	-	2	1	1
systemic sclerosis	-	1	-	-
Systemic vasculitides				
in general	-	-	3	1

**Initial dose: dose at the start of therapy, will often be decreased in time depending on disease activity; doses in prednisone equivalents a day: low: ≤ 7.5 mg; medium: > 7.5 mg but ≤ 30 mg; high: > 30 mg but ≤ 100 mg; very high: > 100 mg.*

–: rare use; 1: infrequent use, for therapy resistant disease, complications, severe flare, major exacerbation, and for bridging the lag-time of recently started therapy; 2: frequently added to/used as the basic therapeutic strategy; 3: basic part of the therapeutic strategy.

CPP, calcium pyrophosphate.

4.1 Main therapeutic aims

4.1.1 Immunosuppression, symptomatic effect

Apart from immunosuppression in collagen diseases and vasculitides, in which glucocorticoids are anchor drugs, glucocorticoids as adjunctive therapy are effective in relieving symptoms (pain, stiffness, functional limitation) in RA and many other types of arthritis. A review provided evidence of short-term benefit in RA, with a large effect size on pain. However, long-term benefit is less impressive: a review of seven studies (253 patients in total) evaluating the symptomatic effect of glucocorticoids in RA concluded that, when administered for a period of about 6 months, they had a moderate effect size (standardised mean difference) for pain of 0.43 (Criswell et al, 2000). Improvement has also been documented regarding several other clinical parameters, including joint scores, morning stiffness and fatigue, but also regarding acute phase reactants, such as erythrocyte sedimentation rate and C reactive protein. Although after 6 months of therapy the clinically beneficial effects of glucocorticoids in general seem to diminish, many clinicians report that if this therapy is then tapered off or stopped, patients may experience aggravation of symptoms. This may indicate suppression of the hypothalamic–pituitary–adrenal axis, but also that the glucocorticoid still was clinically effective after all.

In intensive (tight-control, treat-to-target) treatment strategies in early RA, glucocorticoids are used for rapid disease control, with fast symptomatic improvement besides possible slowing of joint damage for some schemes (see next paragraph). There is reluctance to prescribe the COBRA (Combination therapy for Rheumatoid Arthritis) approach because of high initial doses of glucocorticoids (van Tuyl et al, 2008). However, also the use of lower initial doses of glucocorticoids as in COBRA-light (den Uyl et al, 2014; Ter Wee et al, 2014) and COBRA-slim (Verschuieren et al, 2017), the application of oral short-term medium dose glucocorticoids (start 30 mg prednisone equivalent daily, tapering to zero in 10 or 34 weeks, respectively) or one intramuscular 120 mg methylprednisolone injection (de Jong et al, 2014), and intra-articular glucocorticoid injections into inflamed joints (Axelsen et al, 2014) all showed benefit in treat-to-target approaches in early RA.

4.1.2 Joint sparing effect in early RA

Although glucocorticoids are associated with generalised increased bone loss and increased risk of osteoporotic fractures, they have positive effects on periarticular bone in early RA, as joint-sparing agents. In 2007, a meta-analysis including 15 studies and 1414 patients with early RA showed convincing evidence that glucocorticoids, given in addition to standard disease-modifying antirheumatic drug (DMARD) therapy in dosages of 5–10 mg prednisone equivalents daily for 1–2 years, can substantially reduce the rate of progression of erosive joint damage (Kirwan et al, 2007*). Even if added to a tight-control, treat-to-target methotrexate-based strategy aiming for remission, prednisone still has a joint-sparing, disease-modifying effect, as shown in the second Computer Assisted Management in Early Rheumatoid Arthritis trial (CAMERA-II) (Bakker et al, 2012*). The advantage regarding joint damage in patients who used glucocorticoids during the first years of their disease still is detectable during the following years (Landewé et al, 2002; Jacobs et al, 2006). However, it has not yet been established whether glucocorticoids can also inhibit progression of erosions when started in RA of longer duration, or whether use for longer than 2 years in early RA has additional joint sparing effects compared to use for 1–2 years. . A recent update of the EULAR guidelines to treat RA states that ‘short-term glucocorticoids should be considered when initiating or changing csDMARDs, in different dose regimens and routes of administration, but should be tapered as rapidly as clinically feasible’ (Smolen et al, 2017). The added efficacy of GC when combined with csDMARDs is well established. In the previous EULAR guidelines, glucocorticoids were also dealt with in a recommendation, but the wording was different: ‘low-dose GC should be considered as part of the initial treatment strategy for up to 6 months, but should be tapered as rapidly as clinically feasible’. So ‘low-dose’ was, after a critical discussion and evaluation of the recent literature, changed into ‘short-term’.

4.2 Specific glucocorticoid applications

4.2.1 Pulse therapy

At high and very high dosages, non-genomic effects also come into play, with possible changes in the relative potencies of the different glucocorticoids. For example, methylprednisolone and prednisolone have similar potency in low and medium dosages, but in high dose and pulse therapy the non-specific non-genomic effect of methylprednisolone is more than threefold stronger (Lipworth, 2000). This may explain the empirical clinical preference for methylprednisolone for pulse therapy. This treatment is usually given intravenously and applied for a short period of time (1–5 days). Flares or severe disease activity or complications of rheumatic diseases such as systemic lupus erythematosus (SLE), vasculitis, polymyositis and RA are indications for this therapy. The duration of the effect of pulse therapy for RA flares shows large variation among individuals, but beneficial effects generally last for about 6 weeks. In RA in particular, one should differentiate between actual pulse therapy and short-term use of medium to high doses. The former, defined as doses ≥ 250 mg per day, is mainly

applied in case of severe refractory disease and life-threatening exacerbations whereas doses from 30-60 mg per day with subsequent tapering according to the COBRA scheme are often sufficient when treating non-complicated flares. To maintain the beneficial effect for a longer time, it is sensible to intensify the long-term therapeutic strategy for RA. If this is done when pulse therapy is applied, the glucocorticoid pulse bridges the lag-time of the intensified strategy with DMARD, before its clinical effect becomes apparent. A mitigated form of pulse therapy is the monthly intramuscular use of 120 mg depot methylprednisolone acetate. However, in contrast to oral glucocorticoids, this treatment showed only a small effect on joint erosion progression at the cost of a significant increase in adverse events (Choy et al, 2005).

The incidence of adverse effects of incidental pulse therapy is relatively low and is related to the underlying disease. Osteonecrosis and psychosis as adverse effects are more frequently seen in SLE than in RA, so these complications might (also) be attributable to active SLE, or active SLE could be an additional risk factor for development of these adverse effects.

4.2.2 Intra-articular and intralesional injections

Local injections of glucocorticoids are often used in sterile arthritis, bursitis and tenosynovitis. The effect in sterile arthritis depends on arthritis type—that is, diagnosis, local arthritis activity, the joint treated (size, weight bearing or non-weight bearing), application and efficacy of synovial fluid aspiration before injection (Weitoft and Uddenfeldt, 2000), type and dose of the glucocorticoid preparation, injection technique, and possibly application of rest to the injected joint (Gaffney et al, 1995). However, it is difficult to predict precisely the effect of a local injection in an individual.

The effect of intra-articular injections in osteoarthritis seems to be less consistent compared to that in RA (Hirsch et al, 2013); in RA, almost always a good—albeit temporary—effect is noted. However, in an older, retrospective study among RA patients in whom several different joints were injected, knee joints in particular required at least one additional injection (McCarty et al, 1995). Soluble glucocorticoids compared to insoluble glucocorticoids have a more rapid onset of action with probably less risk of atrophy of the subcutis and depigmentation of the skin, especially when given in superficial structures with tight skin, compared to insoluble glucocorticoids. However, insoluble glucocorticoids like triamcinolone hexacetonide are longer acting (Blyth et al, 1994); they can be applied safely into deep sites. Short-acting soluble glucocorticoids can be mixed with long-acting insoluble ones to combine rapid onset with long duration of effect. Injection of a local anaesthetic concurrently with a glucocorticoid may provide immediate relief of pain and can also be applied to dilute the glucocorticoid concentration to avoid local skin atrophy and to increase the volume for better distribution in larger joints. Accuracy of steroid placement probably influences the clinical outcome of glucocorticoid injections in the shoulder and probably also other joints (Eustace et al, 1997); it has been reported that over half of shoulder injections are inaccurately placed. Ultrasound-guided injection may

improve accuracy and effectiveness of injection therapy (Chen et al, 2006). The effect of post-injection rest on the injected joint is debated. In a randomised controlled study, bed rest for 24 h following injection of a knee joint in patients with arthritis resulted in prolonged duration of the clinical response and reduced the need for additional injections, compared to a control group not receiving bed rest (Chakravarty et al, 1994). Favourable effects of resting the injected joints (eg, by splinting in a cast or plaster) for 3 weeks in case of a non-weight bearing (upper extremity) joint and 6 weeks for a weight bearing (lower extremity) joint have also been described (Blyth et al, 1994), but there are negative study results too. Based on the literature, no definite evidence-based recommendation can be made, but it seems prudent to rest and certainly not to overuse the injected joint during several days after injection, even if pain is relieved.

It is recommended that intra-articular glucocorticoid injections in an individual joint should not be given more frequently than 3–4 times a year, especially if it is a weight bearing joint, to prevent glucocorticoid-induced joint damage. This recommendation seems sensible, but there is no definite clinical evidence to support it.

Local adverse effects of local glucocorticoid injections include subcutaneous fat tissue atrophy, especially after improper local injection, local depigmentation of the skin, tendon slip and tendon rupture, lesions to local structures such as nerves, and microbial infections. The reported infection rate of joints following local injections with glucocorticoids is low and ranges from one case in 13 900 to one case in 77 300 injections (Seror et al, 1999; Gray et al, 1981). Of 214 joints affected by bacterial arthritis (including 58 joints with a prosthesis or osteosynthetic material) in 186 patients in a prospective study over 3 years among a population of more than 1 million, only three joint infections were attributed to an intra-articular injection (Kaandorp et al, 1997*).

Systemic adverse-effects of local glucocorticoid injections include disturbance of the menstrual pattern, hot flush-like symptoms during the day of the injection or the day after, and hyperglycaemia, especially in diabetes mellitus.

4.2.3 Modified-release oral therapy

Circadian rhythms of cortisol are different in patients with inflammatory rheumatic diseases compared to healthy individuals. In RA patients, serum cortisol rises earlier in the night and reaches higher levels (Bijlsma and Jacobs, 2008). These changes are driven by pro-inflammatory cytokines. It may be important to time glucocorticoid therapy according to the circadian rhythm of pro-inflammatory cytokines, which are responsible for signs and symptoms early in the morning at the time of awakening. The efficacy and safety of a modified-release prednisone tablet was studied in patients with active RA, who were randomly allocated to standard prednisone tablets taken in the morning or modified-release prednisone tablets taken at bedtime, which release prednisone after a delay of about 4 h. This modified release is aimed at suppressing the rise of pro-inflammatory cytokines in the night. The modified-release prednisone reduced morning joint stiffness better than standard

prednisone taken in the morning (Buttgereit et al, 2008a). Compared to prednisone, the safety profile seemed similar and there was no statistical difference found in hypothalamus–pituitary–adrenal axis function (Alten et al, 2010). In another open study involving patients with active RA treated with conventional DMARDs and prednisone or 6-methyl-prednisolone, better suppression of disease activity was found after 4 months when switching the glucocorticoid taken in the morning to modified-release prednisone taken at bedtime (Cutolo et al, 2013). Further research is needed, for example, to find out whether this preparation is also effective in other diseases, what the difference is in effect compared to prednisone taken at bedtime, and whether the new preparation also has DMARD properties in early RA, which would be expected.

Summary : Due to the various therapeutic effects of glucocorticoid drugs, administration regimes vary depending on the treated disease. Strong immunosuppressive effects are achieved by applying high doses and pulse therapy for immediate disease control in life-threatening conditions. In contrast, even low doses suffice to improve symptoms and prevent joint destruction in early RA. Modified-release prednisone represents a promising approach to relieve symptoms like morning stiffness that are caused by the circadian rhythm of pro-inflammatory cytokines.

5 Adverse effects

Most published studies on glucocorticoid toxicity are retrospective and observational. The inability to differentiate unfavourable outcomes attributable to glucocorticoids from those occurring as a complication of the disease being treated or comorbidities (Au et al, 2011) severely confounds the picture (figure 5). Furthermore, there is strong bias for glucocorticoid use as physicians are inclined to treat patients with more severe disease with glucocorticoids (allocation or channelling bias). Some information on adverse effects can be extracted from randomised clinical trials, in which selection bias can be ruled out and occurrence of adverse effects in glucocorticoid users can be compared with that of controls. However, most of these studies are focused on therapeutic effects of glucocorticoids with limited reporting of adverse effects.

Compared with other antirheumatic agents, glucocorticoids have a low incidence of short-term symptomatic toxicity and it is uncommon for patients to discontinue therapy for this reason. Despite over 60 years of use, robust data on toxicities of long-term glucocorticoid therapy are sorely lacking. Basically, the risk and spectrum of adverse effects of glucocorticoids seem to depend on the dose and duration of therapy (Huscher et al, 2009; Listing et al, 2013; Widdifield et al, 2013) and patient-specific characteristics (protective but also risk factors) (Strehl et al, 2016). An overview on the most common glucocorticoid adverse effects is provided below (da Silva et al, 2006) (table 4).

Figure 3 Interplay of effects of glucocorticoids and negative disease features. Inflammatory diseases have been proven to exert negative effects on bone mass, lipids, endothelium, glucose metabolism and insulin tolerance, infection risk, and pregnancy outcome. These negative effects are also attributed to (especially medium and high dose) glucocorticoids. Glucocorticoids suppress the inflammatory disease and thus also these negative disease-related effects.

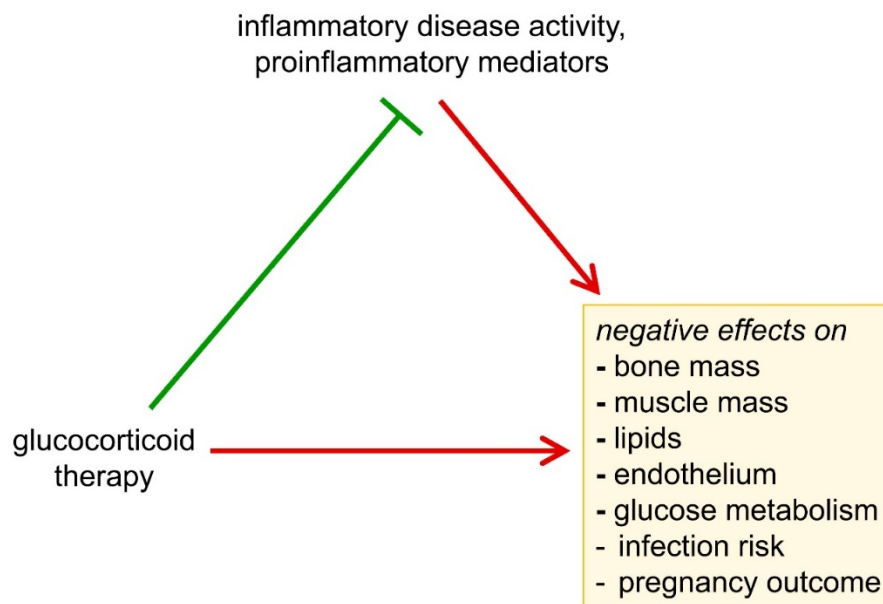

Table 4 Reported adverse effects in glucocorticoid-treated patients with rheumatic diseases

Type of adverse effect	Median (25–75th centiles) number of adverse effects per 100 patient-years of treatment
Cardiovascular (dyslipidaemia, water and electrolyte imbalance, oedema, renal and heart dysfunction, hypertension)	(28–3) 15
Infectious (viral, bacterial, skin infections)	(15–3) 15
Gastro-intestinal (peptic ulcer disease)	(20–4) 10
Psychological and behavioural (mood disturbances)	(236–2) 9
Endocrine and metabolic (glucose intolerance and diabetes, fat redistribution, interference with hormone secretion)	(34–3) 7
Dermatological (skin atrophy, acne, hirsutism, alopecia)	(80–2) 5
Musculoskeletal (osteoporosis, osteonecrosis, myopathy)	(9–3) 4
Ophthalmological (glaucoma, cataract)	(5–0) 4

Summed reported adverse effects (AEs) in 18 studies among patients using glucocorticoids (n = 963) for a rheumatic disease. Data only of studies with patients using glucocorticoids in doses of maximally 30 mg prednisolone equivalent per day and reporting dichotomous adverse effects outcomes were used. Raw data, not corrected for disease activity, comorbidity and the frequency of AEs in the control group (if present) are shown. So, not all negative effects can be specifically attributed to the use of glucocorticoids; common events may be overestimated and less common ones underestimated. AEs were classified into groups and per group expressed as incidence per 100 patient-years (by dividing the number of AEs in a group by the duration of follow-up in years and multiplying by 100). The mean daily dose was 8 mg prednisone equivalent, and the mean duration of the studies was 20 months

Interestingly, the assessment of severity of these adverse effects differs between rheumatologists and patients. In an exercise adverse events were ranked for their importance by both groups. While osteoporosis, diabetes mellitus and cardiovascular effects were ranked within the five most worrisome adverse effects by patients and rheumatologists, the ranking revealed remarkable differences for other adverse effects. For example renal dysfunction, fatigue, palpitations and dyspnoea were ranked as more worrisome by patients compared to rheumatologists (van der Goes et al, 2010a). This exercise reflected concerns about glucocorticoids in both groups, clearly demonstrating that detailed information on the benefits but also risks of glucocorticoids is necessary before start of therapy.

5.1 Cardiovascular adverse effects and events

The development of (premature) atherosclerotic vascular disease as a potential adverse outcome of glucocorticoids is more difficult to study than effects on risk factors for cardiovascular disease. Hypertension is observed in about 20% of patients exposed to exogenous glucocorticoids, but it is related to the dose prescribed and might be less likely with low or medium dose therapy. In patients receiving glucocorticoids in dosages up to 10 mg prednisone equivalent daily, age and elevated pre-treatment blood pressure may better explain significant hypertension than the use of glucocorticoids. Individual variation in susceptibility and other factors, such as the level of starting blood pressure, dietary salt intake, renal function, associated and comorbid diseases, and concomitant drug therapy, are also likely to play a role. While on medium to high doses of glucocorticoid therapy, patients with hypertension require close surveillance of their blood pressure and may need modification of their antihypertensive regimens.

Observational studies on lipids of patients on long-term treatment with medium to high doses of glucocorticoids for renal or cardiac transplants and asthma generally demonstrate elevations in total plasma cholesterol, low density lipoprotein cholesterol, high density lipoprotein cholesterol, and triglycerides. However, the effects of glucocorticoids on lipids seem to be dose-dependent; in two studies in SLE patients, significant changes in lipid levels were seen only at prednisone doses above 10 mg daily. Studies have even suggested that low-dose glucocorticoids may reverse unfavourable lipid changes induced by the inflammatory disease and may decrease the negative effects of chronic inflammation on the vascular endothelium (Garcia-Gomez et al, 2008).

Accelerated atherosclerosis and elevated cardiovascular risk have been reported in patients with SLE and in patients with RA (Peters et al, 2010). Glucocorticoids may increase cardiovascular risk further via their potentially deleterious effects on lipids (Wei et al, 2004), glucose tolerance, insulin production and resistance, blood pressure, and obesity (Peters et al, 2010). However, the development of atherosclerotic vascular disease in RA patients on glucocorticoids has been explored in several studies with inconclusive results. In these studies there could be considerable channelling bias; glucocorticoid doses and other confounding factors such

as disease severity and comorbidity and concomitant drug therapy were not always reported. In a QUEST-RA study, glucocorticoid use was associated with a decreased risk of cardiovascular morbidity (hazard ratio 0.95, 95% confidence interval (CI) 0.92 to 0.98), but this beneficial effect was smaller than that of other DMARDs (Naranjo et al, 2008). In another study in RA, carotid plaque and arterial incompressibility was associated with glucocorticoid exposure, independent of cardiovascular risk factors and RA clinical manifestations (Zampeli et al, 2012). A literature review showed only a trend of an association in RA patients between exposure to less than 10 mg/day of prednisone and the risk of major cardiovascular events (Ruyssen-Witrand et al, 2011). In another study, among glucocorticoid users the risk of cardiovascular diseases was increased in those using at least 7.5 mg prednisolone equivalent daily, but not in those using lower dosages (Wei et al, 2004). In an RA cohort with prospective yearly data assessments, including 779 patients with a total of 7203 patient-years of observation, during which 237 patients died, Cox proportional hazards regression adjusted for potential confounders and for the propensity to receive glucocorticoids was used to assess the hazard ratio of glucocorticoid use for cardiovascular mortality (del Rincon et al, 2014*). Compared to no glucocorticoid use, daily doses up to 7 mg prednisolone equivalent were not associated with a statistically increased hazard rate; the hazard rate at 8–15 mg was 2.3 (95% CI 1.4 to 3.8) and at ≥ 15 mg it was 3.2 (95% CI 1.1 to 9.0). Compared to no glucocorticoid use, cumulative doses up to 39 g were not associated with a statistically increased hazard rate; the hazard rate at ≥ 40 g was 2.1 (95% CI 1.3 to 3.3). Compared to no glucocorticoid use, cumulative doses per year up to 5.07 g were not associated with a statistically increased hazard rate; the hazard rate at ≥ 5.08 g per year was 2.4 (95% CI 1.5 to 3.8).

Taken together, next to inflammatory disease activity, traditional cardiovascular risk factors including comorbidities such as diabetes mellitus, and co-therapies—for example COX-2 selective non-steroidal anti-inflammatory drugs (NSAIDs)—, medium and high glucocorticoid doses and long duration of this therapy are cardiovascular risk factors. EULAR recommendations for cardiovascular disease risk management state that, to prevent cardiovascular disease (and other adverse effects), glucocorticoid should be prescribed in lowest effective dose and for the shortest period possible (Agca et al, 2017).

5.2 Infections

Medium to high dose glucocorticoid therapy, particularly when administered for prolonged periods of time, may lead to an increased risk of serious infections requiring hospitalisations, surgery, or both (Widdifield et al, 2013). Observational studies suggest an increased risk of infection with glucocorticoid therapy, in contrast to randomised clinical trials (Dixon et al, 2011b). Inconsistent reporting of safety outcomes in randomised clinical trials, and heterogeneity, confounding and publication bias in observational studies, impede robustness of conclusions. It is difficult to differentiate the independent effects of glucocorticoid use from those of other commonly used anti-rheumatic agents such as methotrexate and biologicals—for example, anti-tumour necrosis factor agents—and to differentiate adverse effects of glucocorticoid use from negative effects of

disease activity (Au et al, 2011). Retrospective studies using administrative data from Quebec, Canada found an increased risk of non-serious and serious infections associated with glucocorticoid therapy in RA patients aged ≥ 65 years; the risk was dose-dependent and higher than that seen with methotrexate, although confounding could not be fully excluded (Dixon et al, 2011a; Dixon et al, 2012). In another retrospective RA cohort of patients aged ≥ 66 years, there was a clear dose-dependent risk of infections; again bias could not be fully excluded, especially since surrogate markers for disease activity had been used as covariates in the analysis (Widdifield et al, 2013). Pneumocystis infections have been associated with glucocorticoid doses as low as 16 mg prednisone equivalent daily for 8 weeks (Yale and Limper, 1996), and RA patients treated with immunosuppressive agents including glucocorticoids also have a higher risk of acquiring herpes zoster (figure 6). To conclude, in patients treated with glucocorticoids, especially the elderly and those with comorbidities, physicians should anticipate a dose-dependent increased risk of infections with both typical and atypical microorganisms, appreciating that glucocorticoids may blunt classic clinical features of infection due to their anti-inflammatory actions and thus delay the diagnosis.

In order to prevent certain infections, vaccination may be considered. EULAR recommendations for vaccination in patients with autoimmune inflammatory rheumatic diseases (AIIRD) suggest examination of the patient's vaccination status and – if possible – administer recommended vaccinations before starting anti-inflammatory therapy and ideally during stable disease. However, live attenuated vaccines should be avoided in immunosuppressed patients and the risk of triggering flares needs to be considered (van Assen et al, 2010). In general, every patient should also be advised to take infection-preventive hygienic measures.

5.3 Gastrointestinal adverse effects

Glucocorticoids are considerably less toxic to the upper gastrointestinal tract than NSAIDs; glucocorticoids may have dual action on the gastric mucosa, gastroprotective and ulcerogenic (Filaretova et al, 2009). The relative risk of gastrointestinal problems, such as gastritis, ulceration and gastrointestinal bleeding, associated with glucocorticoid use without concomitant NSAIDs has been reported not to be increased (Piper et al, 1991), and to be increased twofold (Garcia Rodriguez and Hernandez-Diaz, 2001), compared to individuals not using glucocorticoids or NSAIDs. The relative risk is about 4 among users of NSAIDs not using glucocorticoids, compared to individuals not using NSAIDs or glucocorticoids (Garcia Rodriguez and Hernandez-Diaz, 2001; American College of Rheumatology, 2008), and is increased further among those using NSAIDs and glucocorticoids combined (Piper et al, 1991; American College of Rheumatology, 2008). These patients should be protected by using a proton pump inhibitor. The gastrointestinal risks of combined use of glucocorticoids (which inhibit selectively COX-2) and COX-2 selective NSAIDs are unknown.

There are case reports of diverticular perforation—possibly as a complication of glucocorticoid associated diverticulitis—but this association has to be confirmed. Glucocorticoids may cause pancreatitis: odds ratio 1.53, 95% confidence interval 1.27-1.84 (Sadr-Azodi et al, 2013), but this negative event may also be a complication of the disease treated, such as vasculitis or SLE. The risk of asymptomatic or symptomatic colonization of the upper gastrointestinal tract with *Candida albicans* is increased in patients treated with inhalation glucocorticoids and in those on systemic glucocorticoids, especially if combination immunosuppressive therapy is applied (Gupta et al, 1994).

5.4 Psychological and behavioural adverse effects

Psychological adverse effects during systemic glucocorticoid therapy are common (Warrington and Bostwick, 2006). Many patients suffering from RA report a slight increase in their overall sense of well-being when starting on low dose glucocorticoid therapy. This is often a temporary effect that appears to be independent of improvement in disease activity. Symptoms of mental and motor restlessness, insomnia, and, especially if on long-term therapy, depression are also observed in patients on glucocorticoids (Warrington and Bostwick, 2006). Memory impairment, particularly in older patients, may occur even at low doses and could relate to hippocampal dependent functions (Keenan et al, 1996). True glucocorticoid psychosis is uncommon at doses <20 mg prednisone/day; it is more frequently seen in patients with SLE than patients with RA. Insomnia and restlessness occur frequently during pulse therapy (Zhao et al, 2013).

5.5 Adverse effects on glucose metabolism

De novo developed frank diabetes as an adverse event of low-dose glucocorticoid therapy is uncommon. The risk of hyperglycaemia seems dependent on dose and duration of glucocorticoid therapy. Short-term

treatment with prednisolone 60 mg or 30 mg per day decreased disease activity without deterioration of glucose tolerance in patients with active RA (den Uyl et al, 2012). In a population-based case–control study among patients using oral glucocorticoids for different indications, the odds ratio of requiring therapy for hyperglycaemia was 1.8 at doses of 1–10 mg prednisone equivalent daily; it was 3 at doses of 10–20 mg, 6 at doses of 20–30 mg, and 10 at doses of 30 mg or more prednisone equivalent daily (Gurwitz et al, 1994).

Patients with diabetes mellitus will commonly have a higher risk of elevated blood glucose levels while taking glucocorticoids. However, ketoacidosis, a frequent and severe complication of type 1 diabetes, is very rare in glucocorticoid-associated diabetes, which is similar to type 2 diabetes (Di Dalmazi et al, 2012).

RA patients on low to medium dose glucocorticoid therapy had similarly decreased insulin sensitivity and β cell function as glucocorticoid-naïve RA patients (Hoes et al, 2011). However, the cumulative dose of glucocorticoids was shown to have a negative impact on glucose tolerance and insulin sensitivity (Hoes et al, 2011). Channelling bias cannot be excluded—for example, glucocorticoid users may have had more active disease than glucocorticoid naïve controls; active disease also negatively affects these parameters of glucose metabolism (Svenson et al, 1988).

5.6 Weight gain, Cushingoid appearance

Weight gain is an adverse effect of long-term endogenous or exogenous glucocorticoid excess, and is of high concern for patients and rheumatologists (van der Goes et al, 2010a). It is a consequence of increased appetite and alterations in fat and glucose metabolism, resulting in an increase of total body and trunk fat. Weight gain associated with low-dose glucocorticoid therapy for inflammatory diseases might, at least partly, also be due to effectiveness of treatment, as active disease has been reported to induce weight loss, possibly by cytokine effects and loss of appetite. In the CAMERA-II trial, mean weight gain among RA patients over 2 years was greater in the placebo-prednisone strategy group compared to the prednisone strategy group: 2.9 kg (SD 4.2) versus 1.3 kg (SD 5.3), respectively (Bakker et al, 2012*). In an additional analysis, the extra weight gain in the prednisone strategy group seemed largely attributable to a better reduction of weight-loss inducing disease activity, rather than this being an adverse effect of prednisone (Jurgens et al, 2013). Weight gain in RA patients on anti-tumour necrosis factor agents seems to be attributable to the same mechanism of suppressing disease activity (Chen et al, 2013).

Characteristic features of long-term high dose glucocorticoid use are moon face (figure 7), centripetal fat accumulation at the trunk (Stewart and Tomlinson, 2002), waist and abdomen with thin extremities—caused by fat redistribution and muscle atrophy—and atrophic skin with multiple ecchymoses (figure 8) and striae (figure 9). The incidence of this iatrogenic Cushing syndrome is dose-dependent and in general becomes evident after at least 1 month of glucocorticoid therapy. In one study, facial puffiness developed in 13% of patients receiving 5–15 mg prednisone equivalent daily for up to 60 days. Slight Cushingoid features may be

observed in over 5% of the patients exposed to ≥ 5 mg prednisone equivalent for ≥ 1 year, but a moon face—which is very troubling to patients—is uncommon at doses below 7.5 mg prednisone equivalent daily.

5.7 Dermatologic adverse effects

Atrophic skin with ecchymoses is a common adverse effect of chronic medium dose glucocorticoid therapy in the lower range and low-dose therapy in the higher range, especially in the elderly. Atrophic skin results from glucocorticoid effects on keratinocytes, fibroblasts and fat tissue. To a lesser extent, hirsutism, acne, striae and thinning of scalp and genital hair may occur (Huscher et al, 2009). In RA-patients on low-to-medium glucocorticoid doses, easy bruising/ecchymosis, skin atrophy and impaired wound healing were associated with current and cumulative glucocorticoid use, whereas there was low occurrence of abnormal stretch marks, acne, perioral dermatitis, alopecia and hirsutism, which were –in this dose range– not associated with glucocorticoid use (Amann et al, 2017). Use of 10 mg prednisone equivalent/day by patients with ankylosing spondylitis was associated with 12.6 events per 1000 patient years for non-infectious cutaneous adverse effects, including acne and easy bruising (Zhang et al, 2015).

5.8 Suppressed hypothalamic–pituitary–adrenal axis

Prediction in the individual patient of suppression of the hypothalamic–pituitary–adrenal axis (HPA axis) and of tertiary adrenal insufficiency is not reliable, but this suppression appears to depend on the dose and duration of glucocorticoid treatment. Also, the extent of HPA axis suppression is determined by the kind of glucocorticoid used. Long-acting preparations like dexamethasone tend to be more suppressive due to their long tissue life (Chrousos et al, 2011). In clinical practice, it seems appropriate to anticipate potential adrenal insufficiency in patients who have received daily 7.5 mg prednisone equivalent or more for at least 3 weeks (Cooper and Stewart, 2003). Acute cessation of therapy then could lead to problems.

Patients with adrenal insufficiency present with obscure symptoms like fatigue, muscle weakness, weight loss, hypoglycaemia, nausea, vomiting, diarrhoea, abdominal pain and mood changes. In adrenal crisis the symptoms are severe, additionally including lethargy, hypotension, consciousness disturbance, seizures and fever (Bayman and Drake, 2017). In the case of acute injury or stress (eg, with surgery), adequate adaptation (ie, increase) of the glucocorticoid dose is important if the current dose is low. Often a temporary increase of the dose to 15 mg/day is sufficient for minor surgery. Ideally, patients should be informed about this possible complication and carry an emergency certificate in case of chronic glucocorticoid therapy.

5.9 Musculoskeletal adverse effects

5.9.1 Osteoporosis

Glucocorticoid-induced osteoporosis is one of the most frequent and potentially devastating complications of prolonged glucocorticoid therapy, if not prevented and treated with effective strategies, including calcium, vitamin D, bisphosphonates (De Nijs et al, 2006*), parathyroid hormone, and denosumab. Without prevention, glucocorticoid treatment can result in rapid and profound reductions in bone mineral density and increased fracture risk, especially during the first 6–12 months of treatment (van Staa et al, 2002*; van Staa et al, 2003*). Glucocorticoid-induced osteoporosis initially affects predominantly trabecular bone at sites such as vertebrae and, with more chronic use, also cortical bone at sites such as the femoral neck.

Comparison of studies examining effects of glucocorticoids on bone is difficult, however, due to differences in timing of initiation of glucocorticoid therapy, variable dosing regimens, different diseases, varying levels of disease activity, different medications (including osteoporosis preventive therapy), use of different bone mass measurement techniques and machines, and disparities between the sites of measurement. Evidence for osteoporotic effects of low dose therapy for 1–2 years in patients with newly diagnosed RA is lacking; it might even be the case that by reducing disease activity which induces osteoporosis (Haugeberg et al, 2005), the development of osteoporosis is inhibited by glucocorticoids in these patients (figure 3). In the CAMERA-II trial, during the 2-year application of 10 mg prednisone daily with osteoporosis preventive therapy, no bone was

lost (van der Goes et al, 2013). In individual patients on prolonged glucocorticoid therapy, the cumulative dose appears to have the strongest predictive value for decreased bone mineral density (van Staa et al, 2002*). Algorithms have been developed to estimate of the future risk of fractures for individual patients, such as the internet tool Fracture Risk Assessment (FRAX; <https://www.shef.ac.uk/FRAX/>), which binary scores glucocorticoid use (yes/no; yes if the patient is currently exposed to oral glucocorticoids or has been exposed to oral glucocorticoids for more than 3 months at a dose of prednisolone equivalent of 5 mg daily or more). Guidance for adjustments of FRAX according to glucocorticoid dosages have been published (Kanis et al, 2011). There are several national and international guidelines on the prevention and treatment of osteoporosis, including in general clinical risk factors (such as age, gender, menopausal status, smoking, patient and family history of osteoporosis and glucocorticoid use) and bone mineral density; in some guidelines, FRAX has been incorporated (Compston et al, 2013).

The precise mechanisms by which glucocorticoids affect bone are still not completely clear, but many mechanisms have been elucidated (Bultink et al, 2013). Glucocorticoids decrease calcium absorption, increase renal calcium loss, diminish sex and growth hormone production, induce muscle wasting (associated with less loading of bone, and thus bone loss, and with falls, leading to fractures), and directly negatively modulate signalling by, for example, receptor activator of nuclear factor kappa B ligand (RANKL) of (pre)osteoclasts (Bultink et al, 2013). This mechanism leads to enhanced osteoclast function and lifespan, resulting in increased bone resorption (figure 10). Consequently, markers of bone resorption are often increased in patients treated with glucocorticoids. Glucocorticoids also directly inhibit osteoblast function and promote apoptosis of osteoblasts, resulting in reduced bone formation; this is likely to be the most important negative effect of glucocorticoids on bone.

Figure 10 Glucocorticoids do negatively influence the bone structure. (A) Bone remodelling is characterized by a balanced system of bone formation and bone resorption depending on RANKL signalling. (B) Glucocorticoids do direct and indirect affect bone remodelling. RANKL signalling is disturbed leading to an increased function of osteoclast and thereby an enhanced bone resorption. RANKL receptor activator of nuclear factor kappa B ligand, OPG osteoprotegerin

Oral doses of prednisone as low as 2.5 mg daily have been shown to suppress levels of serum osteocalcin, a marker of bone formation. Finally, glucocorticoids promote apoptosis of osteocytes. So, the glucocorticoid-induced increased risk of osteoporotic fractures is based on multiple mechanisms, affecting bone mineral density, bone turnover, micro-architecture, collagen content and cross-linking, and other factors such as myopathy leading to a propensity to fall. This is reflected by the finding that at the same bone mineral density, the risk of osteoporotic fractures (figure 11) is higher in patients on glucocorticoids compared to patients not using glucocorticoids (van Staa et al, 2003*).

Figure 11 Osteoporotic mid-thoracic vertebral compression fractures. Radiograph on the left and magnetic resonance image on the right.

5.9.2 Osteonecrosis

Osteonecrosis—that is, avascular necrosis of bone—is an important adverse event of high dose glucocorticoid use; in contrast to osteoporosis, for osteonecrosis the cumulative dose of glucocorticoids seems less predictive than the (average/peak) height of the dose, perhaps owing to osteocyte and osteoblast apoptosis at higher dosages. In a Japanese study of osteonecrosis of the femoral head (figure 12), 35% of all cases was related to glucocorticoid treatment. Osteonecrosis occurs relatively frequently in SLE, attributable to the often higher doses of glucocorticoids applied in this disease, but probably also because SLE itself is a risk factor (Shigemura et al, 2011; Caramaschi et al, 2012). Several other disorders have been labelled as risk factors for osteonecrosis, including haemoglobinopathies, especially sickle cell disease, alcohol abuse, Caisson disease, Gaucher disease, and hypercoagulability states, such as antiphospholipid syndrome. It is not known whether glucocorticoid therapy in patients with these disorders increases the risk of osteonecrosis. Bisphosphonate therapy, especially intravenous therapy, may be complicated by osteonecrosis of the jaw. Glucocorticoid associated osteonecrosis typically, but certainly not exclusively, occurs in the femoral head; it may also be located in the humeral head and bone near the knee. Osteonecrosis rarely occurs in RA patients receiving low dose therapy or in SLE patients with glucocorticoid dosages below 20 mg prednisone equivalent per day. The

most sensitive and specific imaging modality is magnetic resonance imaging; bone scintigraphy is sensitive but not specific for osteonecrosis, and radiography is not sensitive for early osteonecrosis.

5.9.3 Myopathy

Similar to osteonecrosis, myopathy (loss of muscle mass) rarely occurs in patients receiving low dose glucocorticoids. Based upon results of small studies, fluorinated glucocorticoid preparations such as triamcinolone appear to be more closely associated with myopathy than prednisone. Myopathy has been reported to occur after 6 months treatment with a mean dose of 8 mg triamcinolone daily (equivalent dose: 10 mg prednisone) (Strandberg, 1962). In general, however, myopathy occurs at higher doses and with longer duration of treatment. Often, in patients on these doses, the glucocorticoid —increasing protein breakdown and decreasing protein synthesis— is not the only risk factor for myopathy and muscle degeneration; common associated factors are physical disability and catabolic effects of the inflammatory disease treated (Bautmans et al, 2013; Schakman et al, 2013). The diagnosis is mainly clinical, although muscle biopsy may reveal clues; serum creatinine kinase values are not elevated.

Figure 12 Hip osteonecrosis. Severe deformation of the femoral head with cysts and normal joint width, indicative of (late) damage caused by osteonecrosis of the femoral head.

5.10 Ophthalmologic adverse effects

5.10.1 Cataract

Posterior subcapsular cataract is a well-described complication of prolonged glucocorticoid use, and is dose and duration of therapy dependent. This type of cataract is also related to diabetes, and it is not typically age related. Some studies found no minimal safe dose with respect to this complication (Huscher et al, 2009). Others note that cataracts rarely occur in patients taking prednisone below 10 mg daily within the first year of treatment; however, after an average of 7 years, about a third of these patients will have developed cataract. Also cortical cataracts have been associated with glucocorticoid use (Urban and Cotlier, 1986; Klein et al, 2001).

5.10.2 Glaucoma

Glucocorticoid-treated patients may develop mildly increased intra-ocular pressure, which can lead to minor visual disturbances. This ophthalmologic adverse effect is also dose and duration of therapy dependent. The development of frank glaucoma, threatening eyesight, is rare at low dose therapy, and tends to afflict patients who are otherwise predisposed to the condition. A higher risk for glaucoma with glucocorticoids tends to occur in families with primary open-angle glaucoma, suggesting a genetic basis, and in patients with high myopia and diabetes (Tripathi et al, 1999). In these patients, an ophthalmologist should be consulted before and after initiation of therapy even with low dose glucocorticoids. In rheumatology practices, monitoring for glucocorticoid eye toxicity is not yet very common.

5.11 Glucocorticoid use during pregnancy and lactation: adverse effects on the unborn child and baby

The foetus is protected from maternal glucocorticoids via two mechanisms. First, glucocorticoids bound to proteins cannot pass the placenta. Second, the enzyme 11 β -HSD in the placenta converts cortisol and prednisolone into the inactive 11-dehydro-prohormones, cortisone and prednisone, respectively. The prednisolone maternal-to-foetal blood concentration ratio is about 10:1, owing to these mechanisms. In contrast, dexamethasone has little or no affinity for transport proteins and is poorly metabolised by 11 β -HSD in the placenta; the maternal-to-foetal dexamethasone blood concentration ratio is about 1:1 (figure 13). So, if a pregnant woman has to be treated with glucocorticoids, prednisolone is a good choice to protect the unborn child. If the unborn child has to be treated, for example, to induce lung maturation in foetuses at risk of preterm delivery, or to treat congenital heart block associated with maternal Sjögren syndrome, dexamethasone would be indicated. The risk of adverse effects of antenatal exposure to glucocorticoids, such as reduced intrauterine growth and birthweight, neurocognitive adverse effects, and oral cleft, seems dose, duration of therapy and stage of pregnancy dependent (Park-Wyllie et al, 2000). Several studies report conflicting results regarding occurrence of these adverse effects (Wapner et al, 2007; Peltoniemi et al, 2009;

Khalife et al, 2013), but doses of glucocorticoid and indications for this therapy differ between studies. Furthermore, it is difficult to discriminate between the negative effects and complications of the foetal condition treated and the adverse effects of the glucocorticoid therapy (figure 3). It is advised to avoid high doses (1–2 mg/kg prednisone equivalent) in the first trimester of pregnancy (Park-Wyllie et al, 2000; Temprano et al, 2005), whereas low to moderate doses of prednisone seem to be safe (Temprano et al, 2005).

Breastfeeding is generally considered safe for an infant whose mother is taking prednisolone or prednisone, because these glucocorticoids are excreted only in small quantities in breast milk (Ost et al, 1985; American Academy of Paediatrics, 2001). The exposure of the infant seems to be minimised further if breastfeeding is given before the mother takes her daily dose, or if breastfeeding is avoided during the first 4 h after the intake of prednisolone (Ost et al, 1985), because curves of milk and serum concentrations of prednisolone are similar in time (Temprano et al, 2005). Medium and high dosed glucocorticoids may, even when applied as local injection, suppress lactation (Babwah et al, 2013).

Since a lot of autoinflammatory diseases occur in women of childbearing age, glucocorticoid use in pregnancy is an important topic to be approached to avoid misconceptions concerning the risks and benefits of this therapy. Patients complain about a lack of knowledge causing distrust and poor adherence to therapy (van der Goes et al, 2010a).

Figure 13 Glucocorticoid use in pregnancy. Prednisolone and cortisol, bound to corticosteroid binding globulin (CBG), hardly pass the placenta and are quickly inactivated by 11 β -HSD. On the contrary, dexamethasone has little affinity to the binding protein and enzyme and should be applied if treatment of the child is desired.

Summary : Although glucocorticoids are effective in the treatment of rheumatic diseases, these drugs can also trigger a variety of adverse effects. The risk and spectrum of these adverse effects depend on the dose and duration of therapy and patient-specific characteristics. Adverse reactions comprise for example effects on the cardiovascular system and the glucose metabolism, infections and osteoporosis. The complexity of different disease features complicate the assignment of the source of adverse events – is it a cause of the disease or of the drug with which the disease is treated?

6 Prophylactic measures and monitoring

Data on monitoring during glucocorticoid treatment are scarce. Standard good clinical care monitoring that is appropriate for patients with an inflammatory rheumatic disease does not need to be expanded if low-dose glucocorticoids are prescribed, except for monitoring for osteoporosis according to guidelines, and baseline checks for oedema, fasting blood glucose, and risk factors for glaucoma (van der Goes et al, 2010b). Some prophylactic measures have been proven effective in preventing complications of glucocorticoid therapy and may be contemplated at the start of this therapy (Hoes et al, 2007). When the patient has concomitant therapy with a non-selective NSAID or needs such therapy, dependent on the individual patient's cardiovascular risk, a non-selective NSAID with a proton pump inhibitor can be considered, or (switch to) a COX-2 selective NSAID. Also, the risk of osteoporosis can be minimised with calcium, vitamin D and bisphosphonate, if needed, according to national and international guidelines. Before start of chronic glucocorticoid therapy > 20 mg prednisone equivalents per day, clinicians should assess the patient's vaccination history and address deficiencies (Caplan et al, 2017). However, internationally accepted, glucocorticoid-specific guidelines on vaccination are lacking. During therapy, the dose, effect of treatment, and indication to continue glucocorticoid therapy should be regularly checked during treatment. If aiming at symptomatic improvement of symptoms such as pain, stiffness and physical impairment, the glucocorticoid dose should be kept as low as possible. When using low-dose glucocorticoids as a disease-modifying agent in early RA, a stable dose over a longer period of time (ie, 1–2 years) is needed.

In clinical trials, extensive standard monitoring not only contributes to safer treatment of patients, but also helps establish a valid adverse effects profile of glucocorticoids. This will give insights into the real incidence, prevalence and clinical relevance of adverse effects. This is the reason we propose more extensive monitoring for adverse effects in clinical trials (van der Goes et al, 2010b). To assess glucocorticoid-related adverse effects (and glucocorticoid-sparing effects of additional drugs), a glucocorticoid toxicity index has been developed (Miloslavsky et al, 2017).

Summary: Before starting glucocorticoid treatment, patients should be screened for risk factors predisposing to glucocorticoid-related adverse events. Important prophylactic measures to be considered include gastric protection and anti-osteoporotic therapy. General actions to be taken comprise a healthy lifestyle and hygienic measures to prevent metabolic effects and infections respectively.

7 The future

The increasing knowledge on therapeutic but also side effects enables a more sensible use of conventional glucocorticoids. New biological therapies have not and probably will not in the near future replace glucocorticoids as anchor drugs in therapeutic strategies for rheumatic diseases. Increased understanding of the pathophysiology of rheumatic diseases and the different mechanisms of glucocorticoid action provides interesting and sometimes advanced starting points for the development of optimised glucocorticoids; a case in point is the development of a modified-release prednisone tablet (discussed above). Research into development of GR ligands was based on the genomic mechanisms of 'transrepression' and 'transactivation', with the hypothesis that the first mechanism predominantly induces the anti-inflammatory properties of glucocorticoids and the latter mechanism predominantly induces metabolic adverse effects. However, this simplified theory has often been criticized and this seems to be supported by the fact that either study results are available yet (although several clinical trials analysing the efficacy and safety of different SEGAs are completed) or that to date no SEGAs have entered the market.

Other research focused on nitro-steroids, which are capable of releasing low levels of nitric oxide, and long-circulating liposomal glucocorticoids, aimed at enhanced anti-inflammatory properties and reduced unwanted effects. However, the development of nitro-steroids seems to have been stopped (Strehl et al 2017).

Another approach are long-circulating PEG (polyethylene glycol)-liposomes, in which the active drug is enclosed. These substances accumulate at sites of inflammation resulting in very high local glucocorticoid concentration. Animal studies are promising: a single injection of 10 mg/kg liposomal prednisolone revealed a complete remission of the inflammatory response, whereas free prednisolone shows only mild effects, even after repeated daily injections (Metselaar et al, 2003). Results from clinical studies are still missing. There is one clinical trial (NCT02534896 (www.clinicaltrials.gov)) evaluating the efficacy and safety of intravenous PEGylated liposomal prednisolone sodium phosphate compared with intramuscular injections of methylprednisolone acetate in subjects with a flare of disease activity of rheumatoid arthritis. The estimated study completion date is December 2017, thus we will see if the convincing preclinical study data are reflected in these clinical trial.

Genetic developments might, in the future, lead to personalised medicine (Burska et al, 2014), tailoring treatment to the individual patient's genomic information, increasing efficacy and avoiding adverse effects, but this still seems a long way off.

Summary : Although some developments seem to be very promising, the only product which has already entered the market very successfully is the modified-release prednisone. Clinical trial evaluating the efficacy of SEGRAs and liposomal glucocorticoids are still ongoing.

IN-DEPTH DISCUSSION I

Glucocorticoids in pregnancy

Inflammatory autoimmune diseases, such as rheumatoid arthritis and systemic lupus erythematosus, often occur in women of childbearing age. Treatment of these disorders during pregnancy is an important aspect of management. The relative benefits and risks of specific medications to the mother and the foetus depend on the specific clinical context and may be dependent on the stage of pregnancy. Moreover, untreated active disease itself also carries risks, to the mother as well as to the unborn child.

In pregnancy, the administration of glucocorticoids can be beneficial and in some circumstances even life-saving for both mother and foetus. Recommendations based on evidence and expertise suggest that low dose glucocorticoids are safe for the foetus [1;2] but different perspectives on this issue might exist between the patient and the treating physician [3].

Pharmacokinetics

The pharmacokinetics of glucocorticoids in pregnancy remain unclear. During pregnancy, significant pharmacological alterations occur secondary to profound changes in the renal, gastrointestinal and cardiovascular system. Certain obstetrical conditions, such as preeclampsia, diabetes and multiple gestations, are associated with different volumes of distribution, interactions and clearance rates of medications, adding further complexity to the therapeutic use of glucocorticoids.

Metabolism

Oral glucocorticoids are absorbed in the upper jejunum, with peak plasma concentrations between 30 and 100 minutes after ingestion. These drugs bind to plasma proteins, corticosteroid-binding globulin and albumin, and only the free drug fraction is pharmacologically active. Low serum albumin state, as seen in pregnancy, may thus give rise to potentially higher therapeutic but also toxic effects of glucocorticoids with a high affinity for albumin [1].

After administration of a glucocorticoid to the pregnant woman, there is a rapid transfer to the placenta. Glucocorticoids are metabolised by the placental 11β hydroxysteroid dehydrogenase (11β -HSD) into their inactive 11-dehydro-prohormones, but the conversion of prednisolone is particularly effective, deactivating about 87% of an injected dose of prednisolone [4]. In addition, the fetoplacental unit is relatively lacking enzymes that convert the prohormone prednisone into prednisolone [2]. The maternal-to-foetal blood concentration of prednisone is 10-to-1, in comparison to that of hydrocortisone: 6-to-1 and of dexamethasone: 3-to-1. The higher transplacental passage of dexamethasone is due to its little affinity to transport proteins and the poor metabolism of this molecule by the placental 11β -HSD. Thus, foetal exposure is reduced to a minimum if prednisone and prednisolone are used to treat maternal disorders. On the other hand, if foetal therapy is desired, dexamethasone and betamethasone are preferred.

The effect of high-dose or pulse therapy during pregnancy has not been determined, but these doses affect the immune system also via other (non-genomic) mechanisms compared to lower doses; the high doses are associated with a higher risk of adverse-effects, probably also during pregnancy [5].

Safety

For obvious reasons, large controlled studies on the use of drugs in pregnancy, especially during the first trimester, are lacking. Most data available are from animal studies, but their results are not necessarily generalisable to the human context [1]. However, since the introduction of antenatal glucocorticoid prophylaxis in obstetric practice in 1972 to reduce incidence of respiratory distress syndrome in premature infants [6], there is a large body of evidence that this use is safe.

Orofacial clefts

Animal studies showed numerous toxic effects of glucocorticoid administration in pregnant animals: diminished growth of the foetal brain, thymus, spleen, lung, as well as of the placenta, and congenital abnormalities, particularly cleft palate in the rodent foetus [1]. Studies on the effect of glucocorticoid exposure on cleft palate formation in pregnant women show conflicting results. Cases of cleft palate have been described in children after in utero glucocorticoid exposure, but the incidence is rare. A case control study among 1092 infants with orofacial clefts (palate/lip) showed a significantly increased risk associated with maternal glucocorticoid use during the periconceptional period (one month before to three months after conception) [7]. A systematic meta-analysis also reported an overall odds ratio for bearing a child with cleft palate of 3.4 (95% confidence interval 1.97-5.69) in women who used glucocorticoids during pregnancy [8]. In contrast to these observations, no increase in cleft palate was identified in a nationwide cohort study involving 832636 live births in Denmark, in which data of 51973 infants exposed to glucocorticoids during the first trimester of the pregnancy were compared with those of unexposed infants [9].

Suppression of hypothalamic-pituitary-adrenal axis

Hypothalamic-pituitary-adrenal axis suppression in the pregnant woman may be present after approximately 7-10 days administration of 15-20mg of prednisone daily. Labour and delivery should then be covered with stress doses of glucocorticoids. Suppression of the hypothalamic-pituitary-adrenal axis in the newborn exposed intra-uterine to glucocorticoids is infrequent and transient [10].

Other

Other occasionally reported adverse effects of glucocorticoid use in pregnancy are premature rupture of membranes and intra-uterine foetal growth inhibition [11], and a higher relative risk of neonatal hypoglycaemia:

relative risk (95% CI) 1.61 (1.38-1.87) [12]. Glucocorticoid use during pregnancy might increase the risk of several pregnancy-associated maternal complications, such as hypertension, fluid retention and gestational diabetes.

The frequent use of antenatal glucocorticoids to promote foetal pulmonary maturity has provided very useful follow up data showing no long-term detrimental effects regarding physical development or psychological behaviour of children [2, 13]. Possibly, more frequent hospital admissions because of infections during the first years of life are seen in the antenatal 12mg betamethasone-treated group [13]. Thus, the most important implication of intra-uterine exposure to glucocorticoids for the newborn child possibly is a higher susceptibility to infections.

In the EULAR guidelines it is formulated like this without specifying glucocorticoid dosing : “Current evidence indicates no increased rate of congenital malformations. Prednisone/prednisolone can be continued at the lowest effective dose during pregnancy “[14].

Practical guide

Practical recommendations include the following:

1. Use the lowest dose possible to control the disease [13].
2. A once daily dose is preferred to divided doses over the day.
3. Prednisone/prednisolone is product of choice.
4. Pregnant women who received high dose of glucocorticoids before delivery should be watched for eventual suppression of the hypothalamic-pituitary-adrenal function and managed accordingly during labour and delivery.
5. In severe, refractory maternal disease during pregnancy, methylprednisolone pulses may be considered [13].
6. If the mother was treated with glucocorticoids during pregnancy, be aware of a possible higher susceptibility for infections in the newborn.

Breastfeeding

Prednisone and prednisolone are considered safe in breastfeeding mothers since only a small percentage (<10%) of active drug is secreted to breast milk [10]. Medium and high dosed glucocorticoids may, even when applied as local injection, suppress lactation [15].

If a lactating patient requires high dosages of glucocorticoids (>20mg of prednisone a day [1] or in the EULAR guidelines even 50mg a day [13]), not nursing for 4 hours following medication ingestion is suggested [10]; in the early morning, nursing can be done before taking the glucocorticoid.

IN-DEPTH DISCUSSION II

**Effects of glucocorticoids in early rheumatoid arthritis:
fast action and prevention of radiological progression**

During the past two decades, treatment goals in rheumatoid arthritis (RA) have evolved from a concept of symptom control to a concept of disease control.[1] This has resulted in a more intensive therapeutic approach with earlier introduction of disease-modifying anti-rheumatic drugs (DMARDs),[1, 2] which have been proven to reduce structural joint damage. This damage is often evaluated assessing joint space narrowing and bone erosions on radiographs of hands and feet.[3] Not all patients with RA will develop erosions, and therefore it is unclear if the mechanisms of joint inflammation are the same as the mechanisms of joint destruction.[4]

Glucocorticoids have been used in RA for many decades.[8, 9] There are multiple clinical effects of glucocorticoids. These therapeutic effects range from pain relief and disease modifying effects to strong immunosuppressive actions. Low dose glucocorticoid therapy (i.e. ≤ 7.5 mg prednisone equivalent) is effective in relieving symptoms such as pain, stiffness, and functioning. A review provided evidence of short term benefit in RA, with a large effect size of 1.75 on pain.[10]. However, long term benefit on symptom relief was less impressive: a review of 7 studies (253 patients in total) evaluating the symptomatic effect of glucocorticoids in RA concluded that, when administered for a period of approximately 6 months, glucocorticoids had an effect size for pain of 0.43.[11] Improvement has been documented regarding several clinical parameters, including pain scales, joint scores, morning stiffness and fatigue, and also regarding acute phase reactants, such as erythrocyte sedimentation rate and C-reactive protein. Although after 6 months of therapy the clinically beneficial effects of glucocorticoids in general seem to diminish, many clinicians report that if this therapy is then tapered off or stopped, patients may experience aggravation of symptoms.

Although glucocorticoids are associated with generalized increased bone loss and increased risk of osteoporotic fractures, they have positive effects on periarticular bone in early RA (defined as less than 2 years after diagnosis), as joint-sparing agent. The first study able to specifically address this question was published in 1995 and compared two groups of patients with early RA starting on disease modifying therapy with the addition of prednisolone 7.5 mg daily or with placebo (Figure 1).[12, 13] In this study, low dose glucocorticoids caused an early improvement in articular pain and swelling; this was only superior to standard therapy for a few months. Second, radiographic progression, as measured by the Larsen score, was inhibited by low dose prednisolone. Third, clinical symptoms did not change after discontinuation of prednisolone, whereas x-ray progression resumed, see Figure 1.

Figure 1 Mean (95% CI) articular index (upper chart) and Larsen score after log transformation (lower chart) for 75 patients with radiographs at all-time points. Horizontal bars represent the treatment period (disease modifying therapy plus prednisolone 7.5 mg daily or placebo). After two years treatment patients continued a blinded discontinuation regimen taking the tablets on alternate days for two weeks, and then every third day for two weeks. The difference between groups for articular index is significant at 3 months only. The difference between groups for radiographic progression is significant at 1, 2 and 3 years.

Fifteen studies [12, 14-27] have been included in a Cochrane meta-analysis published in 2007.[28] The results of this analysis show clear cut evidence for the ability of glucocorticoids to substantially reduce the rate of radiographic progression in early RA and the authors concluded: “Even in the most conservative estimate, the evidence that glucocorticoids given in addition to standard therapy can significantly reduce the rate of erosion progression in RA is convincing.” Indeed, even including studies with very low doses of glucocorticoids and patients not also taking DMARDs, the average reduction in the rate of progression was almost 70% (Figure 2). This makes glucocorticoids by far the most powerful DMARD in early RA, particularly when used in combination with other DMARDs.

Figure 2 Radiographic (X-ray) progression in patients treated with or without glucocorticoid in six randomized controlled trials lasting 2 years. Glucocorticoids slowed progression over 2 years from 4.87 to 1.54 units, a reduction of 68%.

According to the 2013 EULAR recommendations on the management of RA, low-dose glucocorticoids should be considered as part of the initial treatment strategy (in combination with one or more conventional DMARDs) for up to 6 months, but should be tapered as rapidly as clinically feasible .[5] It has been shown by several studies that in treat-to-target approaches in early RA high doses of glucocorticoids are not necessary, but that the use of low-dose or low-to medium dose glucocorticoids is beneficial. One of these studies is the CAMERA-II trial (second Computer Assisted Management in Early Rheumatoid Arthritis trial).[29] In this study, the effects of the addition of 10 mg prednisone daily to tight control methotrexate-based treatment were studied in patients with early RA. Co-treatment with prednisone instead of placebo led to better control of disease activity, and to reduced erosive joint damage. The mean of maximum doses of methotrexate was lower and the need for biological treatment was less in the prednisone strategy group. Analysing the number of patients experiencing at least once a specific AE during the study, there were no significant differences, except for less patients in the prednisone group experiencing nausea ($p=0.006$), ALAT > upper limit of normal ($p=0.006$), and ASAT > upper limit of normal ($p=0.016$) compared to patients in the placebo group. This could be attributed to the lower mean of maximum doses of methotrexate needed in the prednisone strategy group.

The Cobra-light study shows comparable favourable effects in early RA on disease activity, functional ability and radiological outcome in the COBRA-light strategy (methotrexate 25 mg/week + initial prednisolone dose 30 mg/day), compared to the COBRA strategy (methotrexate 7.5 mg/week, sulfasalazine 2mg/day and initial prednisolone dose 60 mg/day).[30] The tREACH trial is another study showing benefits from medium dose glucocorticoids (start 15mg prednisone daily, tapered to zero in 10 weeks) in early RA.[31] Recent step down strategies in early RA incorporating bridging glucocorticoid therapy, might not only make use of the therapeutic window of opportunity for preventing damage and loss of function but could also help to meet the specific patients preferences in early disease.[32] While current practice and recommendations suggest the early concomitant use of glucocorticoids for severe and poor prognosis patients, new evidence makes clear

that current prognostic markers are insufficient predictors and that step down strategies might be helpful in the initial treatment of every patient.[33;34]

Finally, some very encouraging observations of long term follow up have been reported which raise the possibility that GC might have enduring effects on disease progression long after therapy with GCs has been discontinued.[35-37] During 4 to 5 years of follow up of the COBRA trial, the radiographic progression rate was 8.6 Sharp points per year in those not treated with glucocorticoids during the original study, but was only 5.6 in the patients who had previously been treated with glucocorticoids during the trial.[36] After 11 years of follow up, this difference was still present.[37]

Another study followed patients from the Utrecht trial after they had been treated with 10 mg prednisolone daily or placebo for 2 years.[35] This study showed that during an additional 3 years of follow-up, radiographic scores showed significantly less progression in the original prednisone group than in the original placebo strategy group. This continuing response, years after stopping glucocorticoids, indicates a sustained suppression of radiographic progression in patients with RA, independent of subsequent anti-rheumatic therapy. However, it has not yet been established whether or not glucocorticoids cause additional inhibition of progression of erosions when started in RA of longer duration or when used for more than 2 years in early RA.

Figure 3 Persistent anti-erosive effect of glucocorticoids in rheumatoid arthritis. There is a persistent reduction in the rate of erosion progression, even after treatment has been stopped. This benefit persists for several years.

Summarizing, glucocorticoids can be classified as DMARDs in early RA, since they have been proven effective in retarding the progression of erosive joint damage in multiple clinical trials. Inclusion of glucocorticoids is

beneficial, specifically in modern tightly controlled treatment regimens for early RA providing rapid benefit, and the effect on damage prevention seems to persist after quitting glucocorticoid treatment.

Treatment Tip

Based on the evidence reviewed here, low-dose and medium dose glucocorticoids should be considered as part of the initial treatment strategy in early RA (in combination with one or more conventional DMARDs) for up to 2 years. Effective retardation of the progression of erosive joint damage in early RA has been proven for dosages of 5 to 10 mg prednisone equivalent daily and for the COBRA and the COBRA light schemes, starting with 60 mg and 30 mg prednisone equivalent daily, respectively and rapidly tapering to stop at 28 weeks. Consultation time will be required to educate patients, their relatives and their primary care physicians about the nature of the treatment and the necessity of careful monitoring during treatment. Recommendations on the management of RA and glucocorticoid therapy can be of help in this situation.[5-7]

Cryoglobulinaemia and Hepatitis C Virus

Pauline Baudart, Christian Marcelli, Clodoveo Ferri

A previous version was coauthored by Clodoveo Ferri, Maria Teresa Mascia, David Saadoun, Patrice Cacoub and Marco Sebastiani

LEARNING OBJECTIVES

- Correctly classify/diagnose cryoglobulinaemia and mixed cryoglobulinaemia (MC).
- Use the correct technical procedures to detect and characterise cryoglobulins.
- Describe and explain the main mechanisms involved in the aetiopathogenesis of MC syndrome (cryoglobulinaemic vasculitis).
- Outline the epidemiology, prognosis and main clinical manifestations of MC syndrome.
- Make a differential diagnosis between MC syndrome and other autoimmune rheumatic disorders (Sjögren's syndrome, rheumatoid arthritis, other systemic vasculitides).
- Define the main organ, systemic autoimmune disorders, and neoplastic complications possibly triggered by hepatitis C virus (HCV) infection, the HCV syndrome.
- Describe and explain the pathogenetic mechanisms of HCV-related autoimmune and lymphoproliferative disorders.
- List the main levels of intervention (etiological, pathogenetic, and symptomatic) and targets of HCV-mixed cryoglobulinaemia therapy: clinical response (organ target manifestations), virological response (HCV RNA) and immunological response (cryoglobulinaemia, C4 serum level).
- Understand that antiviral therapy is the cornerstone of HCV-mixed cryoglobulinaemia treatment.
- State that B cell depleting therapy (rituximab) is an interesting additional therapeutic option.
- Explain the timing of action and the limitations of rituximab.
- Explain concerns about immunosuppressant agent use in HCV-related mixed cryoglobulinaemia.
- Describe the use of steroids, immunosuppressant agents and plasmapheresis.

1 Cryoglobulinaemia

1.1 Definition

The presence in the serum of one (monoclonal cryoimmunoglobulinaemia) or more immunoglobulins (mixed cryoglobulinaemia, MC), which precipitate at temperatures below 37°C and redissolve on rewarming, is termed cryoglobulinaemia or cryoimmunoglobulinaemia and is an in vitro phenomenon (figure 1) (Ferri, 2002*; Ferri, 2008*). Various hypotheses have been suggested to explain the cold precipitation of immunoglobulin(s): it can be secondary to the intrinsic characteristics of both mono- and polyclonal immunoglobulin (Ig) components or can be caused by interaction among single components of the cryoprecipitate. However, the intimate mechanism(s) of cryoprecipitation remains obscure.

Figure 1 Comparison of cryoglobulinaemic and normal serum samples. Cryoprecipitate, evaluated after 7 days' storage at 4°C, is present in a serum sample from a patient with mixed cryoglobulinaemia compared with normal serum (left).

1.2 Classification

Cryoglobulinaemia is usually classified into three subgroups according to immunoglobulin composition (table 1). Type I cryoglobulinaemia consists of only one isotype or subclass of immunoglobulin. Both type II and type III mixed cryoglobulins are immune complexes (IC) composed of polyclonal IgGs, autoantigens and mono- or polyclonal IgMs, respectively; the IgMs are the corresponding autoantibodies with rheumatoid factor (RF) activity. With more sensitive methodologies (ie, immunoblotting or two-dimensional polyacrylamide gel electrophoresis), type II mixed cryoglobulins often show a microheterogeneous composition; in particular, oligoclonal IgM or a mixture of polyclonal and monoclonal IgM can be detected (Ferri, 2002*; Ferri, 2008*). This particular serological subset, termed type II–III MC, could represent an intermediate, evolutive state from

type III to type II MC. Moreover, type II–III MC could fit together with the most recent molecular studies showing the presence of oligoclonal B lymphocyte proliferation in liver and bone marrow biopsy specimens from patients with MC. In two-thirds of patients with type II MC, a cross-idiotype WA monoclonal RF (first isolated from the serum of a patient with Waldenström’s macroglobulinaemia) has been demonstrated (Ferri, 2002*; Ferri, 2008*).

Table 1 Classification and clinico-pathological characteristics of different cryoglobulinaemias

Classification	Composition	Pathological findings	Clinical associations
Type I cryoglobulinaemia	Monoclonal Ig, mainly IgG, or IgM, or IgA self-aggregation through Fc fragment of Ig	Tissue histological alterations of underlying disorder	Lymphoproliferative disorders: MM, WM, CLL, B-NHL
Type II mixed cryoglobulinaemia	Monoclonal IgM (or IgG, or IgA) with RF activity (often cross-idiotype WA-mRF) and polyclonal Ig (mainly IgG)	Leucocytoclastic vasculitis B lymphocyte expansion with tissue infiltrates	Infections (mainly HCV), autoimmune/lymphoproliferative disorders, rarely ‘essential’
Type II–III mixed cryoglobulinaemia	Oligoclonal IgM RF or mixture of poly/monoclonal IgM (often cross-idiotype WA-mRF)	Leucocytoclastic vasculitis B lymphocyte expansion with tissue infiltrates	Infections (mainly HCV), autoimmune/lymphoproliferative disorders, rarely ‘essential’
Type III mixed cryoglobulinaemia	Polyclonal mixed Ig (all isotypes) with RF activity of one polyclonal component (usually IgM)	Leucocytoclastic vasculitis B lymphocyte expansion with tissue infiltrates	Infections (mainly HCV), more often autoimmune disorders, rarely ‘essential’

B-NHL, B cell NHL; CLL, chronic lymphocytic leukaemia; HCV, hepatitis C virus; Ig, immunoglobulin; MM, multiple myeloma; NHL, non-Hodgkin’s lymphoma; RF, rheumatoid factor; WM, Waldenström’s macroglobulinaemia.

Type I cryoglobulinaemia is usually associated with well-known haematological disorders but is often itself asymptomatic (Ferri, 2002*; Ferri, 2008*). Similarly, circulating mixed cryoglobulins can be detected in a great number of infectious or systemic disorders; generally they represent an isolated laboratory finding with no clinical consequences. In contrast, ‘essential’ MC represents a distinct disorder, which is classified as one of the systemic vasculitides. Cryoglobulinaemic vasculitis (figure 2) is secondary to vascular deposition of circulating IC, mainly cryoglobulins and complement, with the possible contribution of both haemorheological and local factors. According to its clinical and histological features, MC is included in the subgroup of small-vessel systemic vasculitides, which also include cutaneous leucocytoclastic vasculitis and Henoch–Schönlein purpura (table 2).

Table 2 Proposed classification of systemic vasculitides

Vessels	Primary	Secondary
Large–medium arteries	Takayasu’s arteritis, giant cell arteritis	Infectious arteritis (syphilis), rheumatoid arthritis
Medium arteries	Kawasaki’s arteritis, polyarteritis nodosa	RA, SLE, SSc, PM/DM, Behçet’s syndrome, HBV+, SS
Medium–small arteries	Granulomatosis with polyangiitis (Wegener’s), eosinophilic granulomatosis with polyangiitis (Churg–Strauss syndrome), microscopic polyangiitis	Cogan syndrome, recurrent polychondritis, drugs, HBV, HCV, HIV infection
Small arteries, capillaries, venules	‘Essential’ MC (<10%),* cutaneous leucocytoclastic vasculitis, Henoch–Schönlein purpura	MC (HCV+ 90%; HBV+ <5%),* HIV infection, others, drugs, lymphoproliferative disorders

*The percentages refer to a Italian mixed cryoglobulinaemia series.

HBV, hepatitis B virus; HCV, hepatitis C virus; MC, mixed cryoglobulinaemia; PM/DM, polymyositis/dermatomyositis; RA, rheumatoid arthritis; SLE, systemic lupus erythematosus; SS, Sjögren’s syndrome; SSc, systemic sclerosis.

Figure 2 Cutaneous manifestations of mixed cryoglobulinaemia (MC). (A) Recent-onset orthostatic purpura; at this stage the histopathological evaluation shows (B) the classic necrotising leucocytoclastic vasculitis characterised by diffuse fibrinoid necrosis and disintegrated neutrophil permeation of the vessel walls. (C) Symmetrical hyperpigmentation of the skin on the legs after repeated episodes of purpura, (D) severe vasculitic manifestation and (E) a large skin ulcer, often resistant to treatment. Both orthostatic purpura (A) and permanent ochraceous lesions (C) are typical skin manifestations of MC.

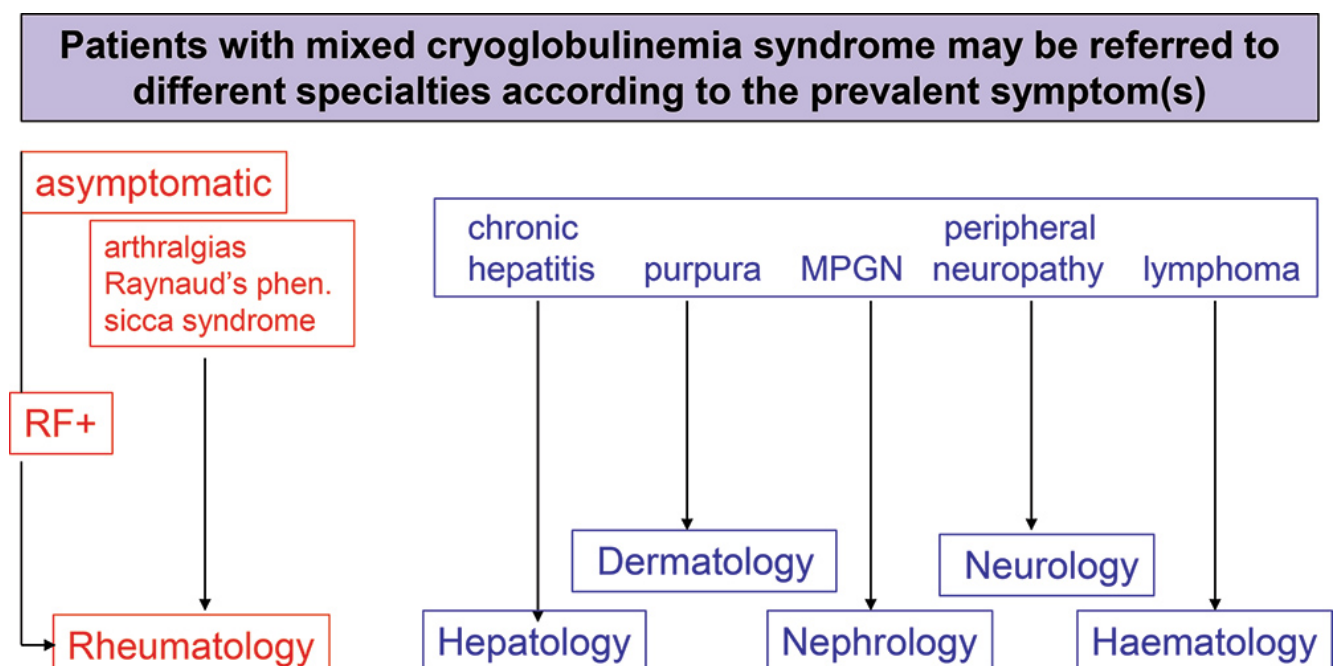

Leucocytoclastic vasculitis is the histopathological hallmark of MC (figure 2). It may involve small- and medium-sized vessels and may be responsible for multiple organ involvement (Ferri, 2002*; Ferri, 2008*). The term ‘cryoglobulinaemic vasculitis’ is often used as a synonym and better describes the typical histopathological alterations commonly detectable in the biopsy of cutaneous lesions.

2 Mixed cryoglobulinaemia (cryoglobulinaemic vasculitis)

2.1 Epidemiology

MC is considered to be a rare disorder, but no adequate epidemiological studies of its overall prevalence have been carried out. Numerous cohort studies of series of patients from different countries suggest that the prevalence of MC is geographically heterogeneous; the disease is more common in southern Europe than in northern Europe or North America. MC is characterised by clinical polymorphism – a single manifestation (skin vasculitis, hepatitis, nephritis, peripheral neuropathy, etc) is often the only apparent or clinically predominant feature – so that patients with MC are often referred to different specialties (figure 3). Consequently, a correct diagnosis might be delayed or overlooked entirely. Thus, we can understand why the true prevalence of MC might be underestimated (Ferri, 2002*; Ferri, 2008*; Ferri, 2016).

Figure 3 Distribution of patients with mixed cryoglobulinaemia (MC) among different medical specialties. Given its clinical polymorphism, MC syndrome may develop with different, often unpredictable symptoms. Consequently, patients with MC may be referred to different specialties according to the prevalent or apparently unique clinical manifestations, such as membranoproliferative glomerulonephritis (MPGN) or purpuric skin lesions. Patients with very mild manifestations, often arthralgias and/or serum rheumatoid factor (RF) positivity, are generally referred to a rheumatology clinic. phen, phenomenon.

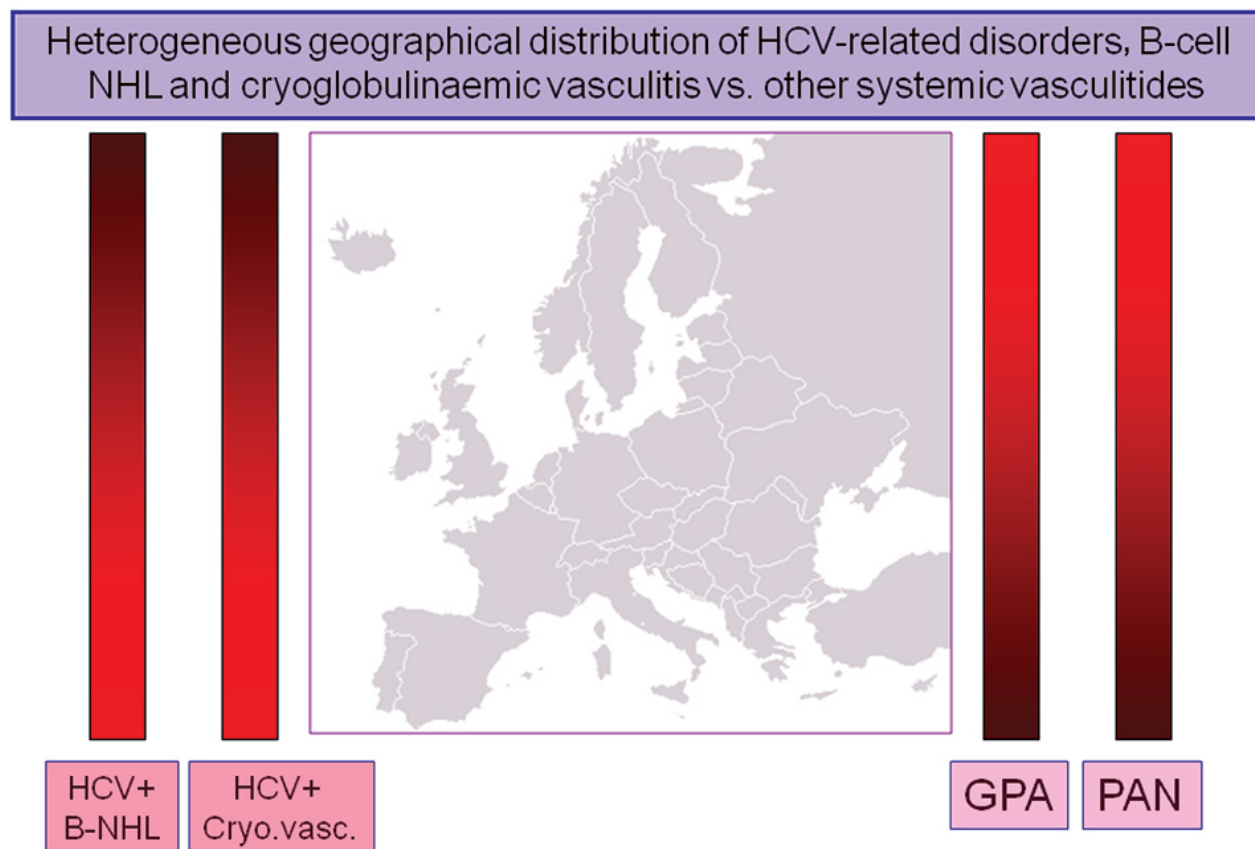

For the above reasons, mainly the frequent dispersion of patients among different specialties, symptom composition in MC syndrome may vary greatly among patient series from various tertiary care facilities (figure

3). Overall, MC is more common in women than in men (female to male ratio of 3:1), disease onset is particularly common in the fourth to fifth decades and in older people, and the disease is rarely seen in young people.

The epidemiology of MC associated with hepatitis C virus (HCV) infection has been examined in cohort studies focusing on HCV-infected subjects, which reported low levels of circulating mixed cryoglobulins in over 50% of cases, while overt cryoglobulinaemic syndrome developed in about 5%. HCV infection is particularly diffuse worldwide; therefore, an increasing incidence of some late complications of HCV infection, such as MC, could be observed, especially in underdeveloped countries where HCV is prevalent in the general population.

In contrast, 'essential' MC is generally seen in a significantly lower proportion of patients with MC, being quite rare in some geographical areas, such as southern Europe (figure 4).

Figure 4 Geographical distribution of some hepatitis C virus (HCV)-related and non-HCV-related disorders. The prevalence of HCV-related disorders, such as mixed cryoglobulinaemia (cryoglobulinaemic vasculitis (Cryo. vasc.) and B cell non-Hodgkin's lymphoma (B-NHL)) shows large geographical heterogeneity. For example, these disorders are more prevalent in southern than in northern Europe, in contrast to the distribution seen for other diseases, such as some systemic vasculitides (granulomatosis with polyangiitis (GPA) and polyarteritis nodosa (PAN)).

2.2 Aetiopathogenesis

Several clinico-epidemiological studies reported that chronic hepatitis was one of the most common symptoms of MC; its prevalence progressively increases to over two-thirds of patients during the clinical course of the disease. This observation suggested a possible role for hepatotropic viruses in the pathogenesis of the disease and so a causative role for hepatitis B virus (HBV) has been sought since the 1970s. The same virus has been just correlated with another systemic vasculitis, namely, polyarteritis nodosa. However, HBV viraemia was rarely recorded, while anti-HBV antibodies varied among different groups of patients with MC (Ferri et al, 2002*; Ferri, 2008*). HBV may be a causative factor of MC in <5% of people (figure 5).

Figure 5 Schematic representation of different clinical and virological subsets of mixed cryoglobulinaemia (MC) syndrome. (1) 'Essential' MC (EMC); (2,3) EMC and hepatitis C virus (HCV)-associated MC syndrome in the setting of definite autoimmune-lymphoproliferative disorders (ALD), such as autoimmune hepatitis, Sjögren's syndrome or B cell lymphomas; (4) the most common subset of HCV-associated MC syndrome; and (5) MC associated with other infectious agents such as hepatitis B virus (HBV).

In 1989, the discovery of HCV as the major aetiological agent of non-A-non-B chronic hepatitis, was crucial for the aetiopathogenetic studies of MC syndrome. A possible role of HCV infection in MC was proposed independently by two pioneering reports which showed a significantly higher prevalence of serum anti-HCV antibodies in these patients than in the general population (Ferri, 2015* review). This hypothesis was deeply confirmed in 1991, when the presence of HCV RNA was detected by polymerase chain reaction (PCR) in 86% of Italian patients with MC (Ferri, 1991*). Following this, an increasing number of studies including clinico-epidemiological observations, as well as both histopathological and virological investigations (HCV RNA detection by PCR and/or in situ hybridisation) established the important role of HCV in the pathogenesis of MC. The prevalence of serum anti-HCV antibodies and/or HCV RNA in patients with MC ranged from 70% to almost 100% among different patient populations. Given the striking association between MC and HCV infection, the term 'essential' is now used to refer to a minority of patients with MC (in Italy <10%; figure 5) (Ferri, 2002*; Ferri, 2008*).

The clinical development of MC is closely linked to the natural history of chronic HCV infection. MC phenotypes are also the result of genetic and/or environmental cofactors, which remain largely unknown (figure 6). HCV has been recognised to be both a hepato- and lymphotropic virus, as suggested by the presence of active or latent viral replication in the peripheral lymphocytes of patients with type C hepatitis or MC. HCV is an RNA virus without reverse transcriptase activity; therefore, the viral genome cannot integrate in the host genome. It is probable that HCV chronically stimulates the immune system through different viral proteins, such as core protein. Chronic stimulation of the lymphatic system exerted through viral epitopes, autoantigen production and/or a molecular mimicry mechanism has been suggested. In this respect, particularly interesting is the presence, in HCV-positive patients, of anti-GOR antibodies, which are cross-reactive autoantibodies directed both to the HCV core and a nuclear antigen called GOR. Another pathogenetic hypothesis suggested that HCV, in association with very low-density lipoprotein (LDL), might induce a T-independent primordial B cell population, producing monoclonal immunoglobulin with WA idiotype. In turn, HCV–very LDL complexes may trigger RF production as a consequence of somatic mutations of WA clones; the possible evolution to B cell lymphomas might be the consequence of the accumulation of stochastic genetic aberrations. The chronic stimulation of B lymphocytes by HCV epitopes may cause expansion of some B cell subpopulations with favourable and/or dominant genetic characteristics (Ferri et al, 2002*; Ferri, 2008*). This hypothesis recalls the pathogenetic role of *Helicobacter pylori* in MALT lymphoma of the stomach, for which different evolutive phases are required.

The interaction between the HCV E2 envelope protein and CD81 molecule, a ubiquitous tetraspannin present on the surface of B cells, may represent another important pathogenetic factor in MC. The consequence of this interaction may be a strong and sustained polyclonal stimulation of the B cell compartment (figure 6). A following pathogenetic step of HCV-related autoimmune-lymphoproliferative disorders may be the t(14;18) translocation found in B cells of HCV-infected subjects. Even if not definitely confirmed, the t(14;18) translocation may lead to increased expression of Bcl-2 protein with consequent inhibition of apoptosis and abnormally prolonged B cell survival. Interestingly, a significantly high prevalence of t(14;18) translocation is found in patients with HCV-related MC (85% in type II MC), and also in patients with isolated hepatitis type C (about 37–38%). It can be hypothesised that during chronic HCV infection, several factors (including the interaction between the HCV E2 protein and CD81 molecule, the high viral variability and the persistent infection of both hepatic and lymphatic cells) may favour a sustained and strong B cell activation (figure 6). This latter may in turn favour the t(14;18) translocation and Bcl-2 overexpression; the consequent B lymphocyte expansion is responsible for autoantibody production, including the cryoglobulins. In addition, the prolonged B cell survival may represent a predisposing condition for further genetic aberrations, which may lead to frank B cell malignancy as a late complication of MC syndrome (Ferri et al, 2002*; Ferri, 2015*).

Of interest, HCV-driven lymphoproliferation may also explain the pathogenetic role of HCV infection in 'idiopathic' B cell lymphomas. This association was first described in unselected Italian patients with idiopathic B cell lymphomas and later confirmed by different epidemiological and laboratory studies, mainly in the same geographical areas as those in which HCV-associated MC is commonly found (figure 4).

Given its biological characteristics, HCV may be involved in many autoimmune and lymphoproliferative disorders. Figure 6 summarises the main causative factors – infectious, toxic, genetic and/or environmental – that are potentially involved in the pathogenesis of MC. These factors, alone or in combination, may trigger two multistep pathogenetic processes, not mutually exclusive, responsible for MC and other HCV-related disorders. The first process produces a 'benign' polyoligoclonal B lymphocyte proliferation responsible for organ- and non-organ-specific autoimmune disorders, including immune-complex-mediated cryoglobulinaemic vasculitis; the second is characterised by different oncogenetic alterations, which ultimately may lead to malignant complications. Comparable pathogenetic mechanisms could be also hypothesised for HCV-negative MC; this intriguing clinical subset might be correlated with other infectious agents or associated with some well-known autoimmune/rheumatic or lymphoproliferative disorders (figures 5 and 6) (Ferri et al, 2002*; Ferri, 2015*).

MC with or without overt clinical syndrome has been reported in patients with a great number of infectious agents, usually as anecdotal observations. A significant prevalence of MC has been found in patients with human immunodeficiency virus (HIV) infection, with and without HCV co-infection. HIV alone may exert a continuous antigenic stimulation of B lymphocytes; these latter may be responsible for type III MC production earlier in the course of HIV infection. In some patients, the B cell disorder may evolve into monoclonal MC with a typical clinical syndrome. As observed for HCV infection, the prevalence of other virus-related MC is variable among patient series from different geographical areas (figure 4). Moreover, a number of clinico-epidemiological studies showed a heterogeneous distribution of different HCV-related extrahepatic manifestations, including some autoimmune disorders such as primary Sjögren's syndrome (pSS) (Ferri et al, 2002*; Ferri et al, 2007*; Ferri, 2015*).

Cryoglobulinaemic syndrome may share a number of aetiopathogenetic events and clinical features with both autoimmune diseases such as autoimmune hepatitis (AIH), Sjögren's syndrome and polyarthritis, and B cell lymphomas. Therefore, a differential diagnosis should be carefully made in all patients with MC syndrome (figure 7) (see also section 2.5); correct disease classification may decisively affect the overall clinico-therapeutic approach and prognosis.

Figure 6 Aetiopathogenesis of mixed cryoglobulinaemia (MC) and other HCV-related disorders: the HCV syndrome. The figure summarises the putative mechanisms involved in the aetiopathogenetic cascade of MC and other HCV-related disorders. This is probably a multifactorial and multistep process: the remote events include some infectious agents, mainly HCV (see also Fig. 5), predisposing host factors and, possibly, unknown environmental/toxic triggers. Viral antigens (eg, HCV core, envelope E2, NS3, NS4, NS5A proteins) may exert a chronic stimulus on the host immune system through specific lymphocyte receptors, such as CD81, which may interact with the viral E2. Predisposing host factors may include particular HLA alleles, and metabolic and hormonal conditions. The main consequence is a 'benign' B cell proliferation with a variety of autoantibodies produced, among which are rheumatoid factor (RF), and cryo- and non-cryoprecipitable immune complexes (IC). These serological alterations may be correlated with different organ- and non-organ-specific autoimmune disorders, including MC syndrome (or cryoglobulinaemic vasculitis). Moreover, the activation of Bcl2 proto-oncogene, responsible for prolonged B cell survival, may be a predisposing condition to other genetic aberrations, which may lead to frank B cell lymphomas and other malignancies. The appearance of malignant neoplasias can be seen in a small but significant percentage of patients, usually as a late complication. Both immunological and neoplastic disorders show a clinico-serological and pathological overlap. Often, autoimmune organ-specific manifestations may evolve to systemic conditions, such as MC, and less frequently to overt malignancies (right). Conversely, it is not uncommon that patients with malignancies develop one or more autoimmune manifestations. In this scenario, MC syndrome is at the junction between autoimmune and neoplastic disorders. HCV, hepatitis C virus; IC, immune complexes; PCT, porphyria cutanea tarda; RF, rheumatoid factor; sicca s., sicca syndrome.

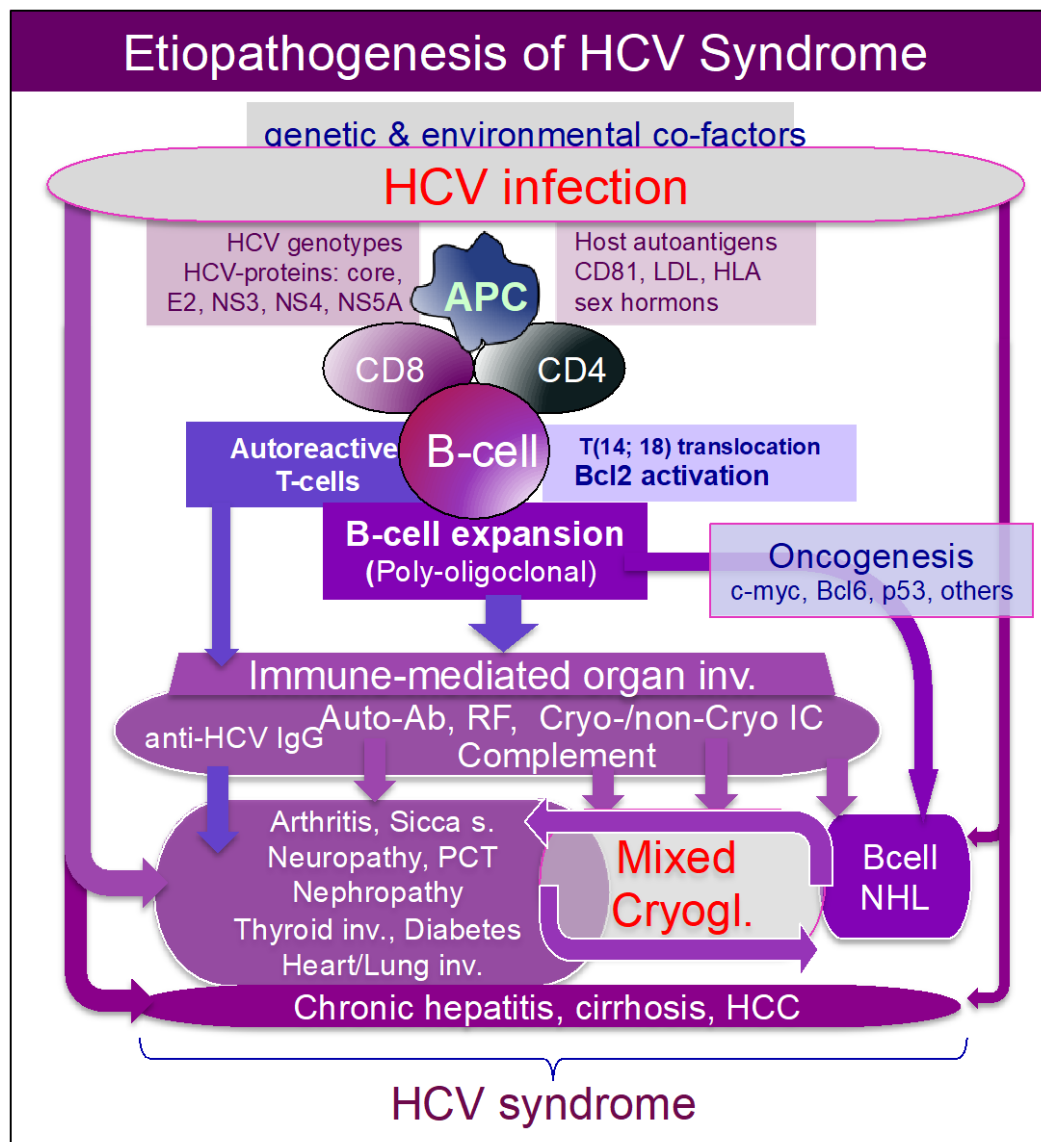

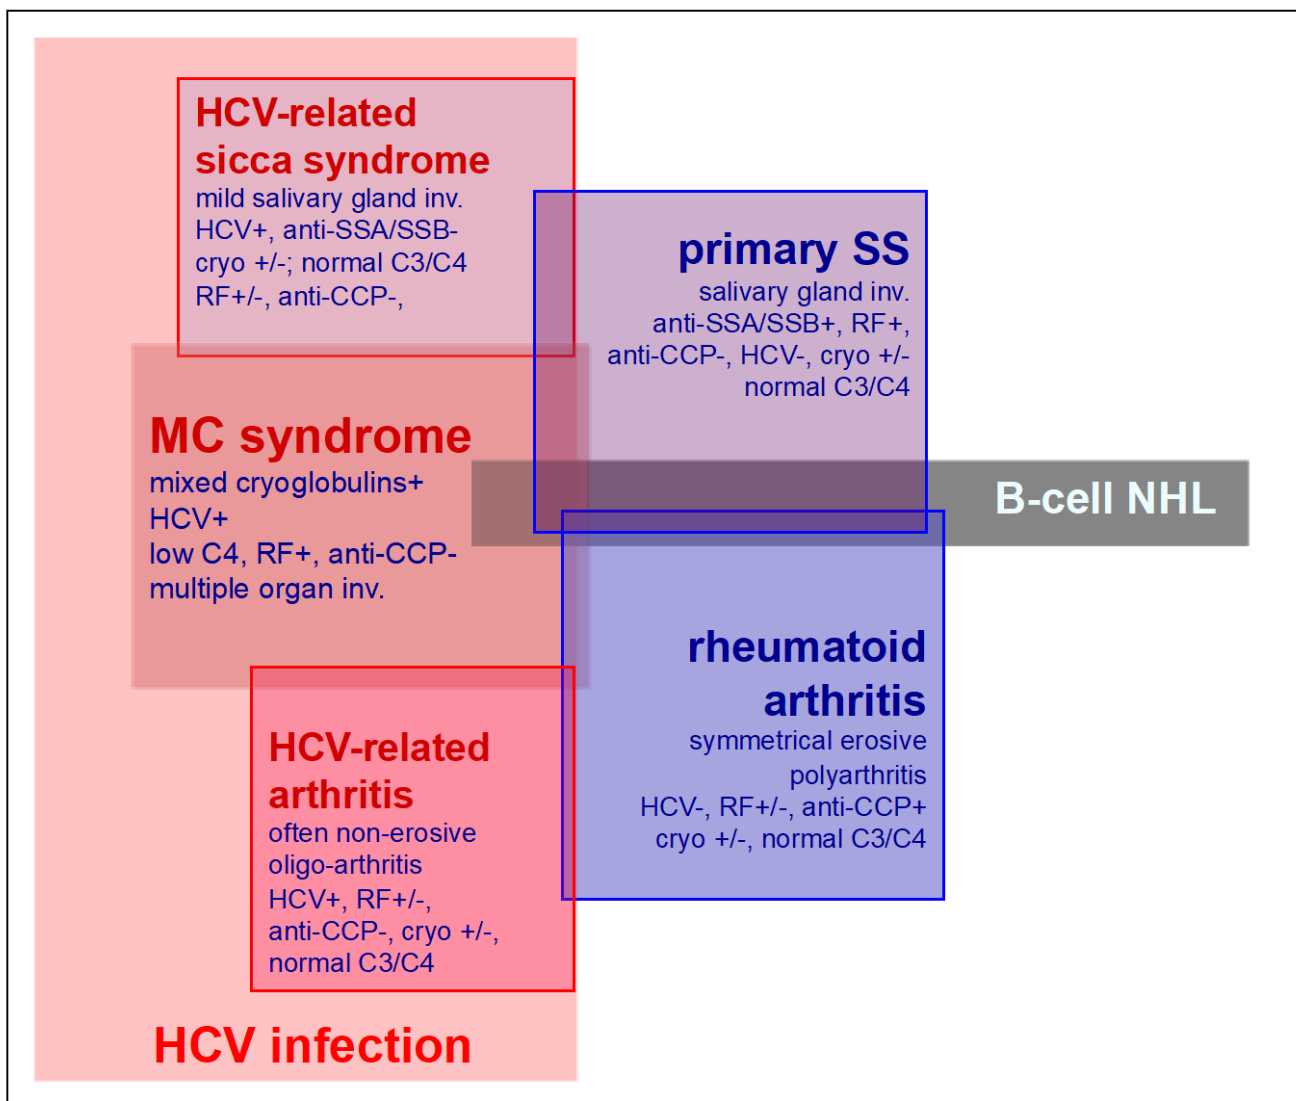

Figure 7 Clinical overlap and differential diagnosis among some possible hepatitis C virus (HCV)-related rheumatic diseases. Mixed cryoglobulinaemia (MC) syndrome, primary Sjögren's syndrome (SS) and rheumatoid arthritis (RA) show a clinico-pathological overlap, including a possible association with HCV infection. The following information may be useful for a correct differential classification/diagnosis: primary SS shows a typical histopathological pattern of salivary gland involvement (inv.) and specific autoantibodies (anti-RoSSA/LaSSB), which are rarely found in patients with MC; conversely, cutaneous leucocytoclastic vasculitis, visceral organ involvement (glomerulonephritis, hepatitis), low C4 and HCV infection, are typically found in MC. Moreover, erosive symmetrical polyarthritis and serum anticyclic citrullinated peptide antibodies (anti-CCP) characterise classic RA. Finally, B cell non-Hodgkin's lymphoma (B-NHL) may complicate these diseases, more frequently MC and primary SS. B-NHL may be suspected following careful clinico-serological monitoring and diagnosed by bone marrow/lymph node biopsies and total body CT scan. RF, rheumatoid factor.

2.3 Clinical manifestations

MC syndrome, or cryoglobulinaemic vasculitis, is characterised by a clinical triad of purpura, weakness and arthralgias, and by a variable combination of symptoms, including chronic hepatitis, membranoproliferative glomerulonephritis (MPGN), peripheral neuropathy, skin ulcers, diffuse vasculitis and, less frequently, lymphatic and hepatic malignancies. The clinical pattern of cryoglobulinaemic vasculitis is comparable in

patients with type II or type III MC. Table 3 gives the prevalence of MC manifestations in an Italian patient population referred to our university-based division of rheumatology. Patient recruitment at different specialist centres may influence the symptom composition of MC series; for example, patients with MC recruited at nephrology units naturally show a higher percentage of glomerulonephritis compared with those seen at rheumatology units (figures 3 and 13). This factor together with the different geographical origins of patient series reported in the literature may be responsible for the variable prevalence of individual MC symptoms (Ferri, 2015*).

Table 3 Demographic, clinico-serological and virological features of 250 patients with mixed cryoglobulinaemia evaluated at the end of patient follow-up

Features	Value
Epidemiological features	
Age at disease onset (years), mean (SD) (range)	54 (13) (29–72)
Female:male ratio	3
Disease duration (years), mean (SD) (range)	12 (10) (1–40)
Clinical features	
Purpura	98
Weakness	98
Arthralgias	91
Arthritis (non-erosive)	8
Raynaud's phenomenon	32
Sicca syndrome	51
Peripheral neuropathy	81
Renal involvement*	31
Liver involvement	73
B cell non-Hodgkin's lymphoma	11
Hepatocellular carcinoma	3
Serological and virological features	
Cryocrit (%), mean (SD)	4.4 (12)
Type II/type III mixed cryoglobulins	2/1
C3 (mg/dL), mean (SD) (normal 60–130)	93 (30)
C4 (mg/dL), mean (SD) (normal 20–55)	10 (12)
Antinuclear antibodies	30
Antimitochondrial antibodies	9
Antismooth muscle antibodies	18
Antiextractable nuclear antigen antibodies	8
Anti-HCV antibodies ± HCV RNA	92
Anti-HBV antibodies	32
HBsAg	1
HCV-/HBV-	7

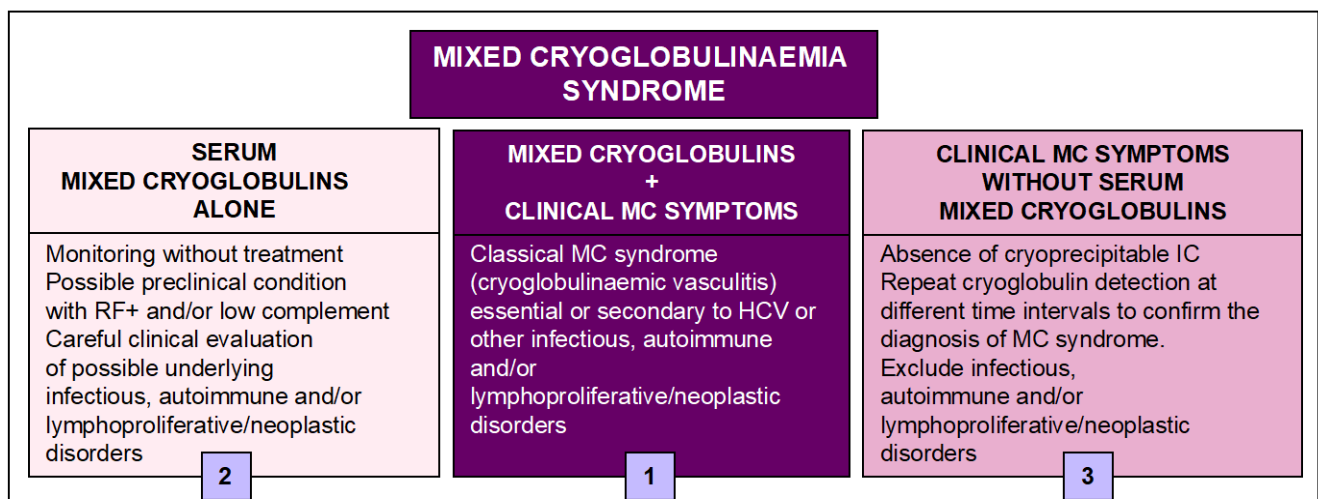

Results are shown as percentages unless otherwise stated.

*Invariably membranoproliferative glomerulonephritis.

HBV, hepatitis B virus; HCV, hepatitis C virus.

At patient anamnesis, the presenting symptoms of MC vary greatly among cryoglobulinaemic patients; similarly, at the first examination, MC shows different clinico-serological patterns, varying from apparently isolated serum mixed cryoglobulins, in some cases associated with mild manifestations such as arthralgias and/or sporadic purpura, to severe cryoglobulinaemic syndrome with multiple organ involvement (figure 8). The disease shows a combination of serological findings (mixed cryoglobulins with RF activity and frequently low C4) and clinico-pathological features (purpura and leucocytoclastic vasculitis with multiple organ involvement). In some chronically HCV-infected subjects, asymptomatic serum mixed cryoglobulins can be found. This condition may precede the clinical onset of disease by years or decades. On the other hand, some patients show typical cryoglobulinaemic syndrome without serum cryoglobulins, the hallmark of the disease (figure 8). MC is characterised by a large amount of cryoprecipitable IC, with the cryoglobulins representing a variable percentage of them among different patients as well as in the same patient during follow-up. Therefore, the absence of serum cryoglobulins may be a transient phenomenon owing to this variable percentage of cryoprecipitable IC; repeated cryoglobulin determinations are necessary for a correct diagnosis in these subjects (Ferri et al, 2002*; Ferri, 2008*).

Figure 8 Different clinico-serological patterns of mixed cryoglobulinaemia (MC). (1) *Definite MC syndrome (or cryoglobulinaemic vasculitis) is a combination of serological findings (mixed cryoglobulins with rheumatoid factor (RF) activity and often low C4) and typical clinico-pathological features (purpura, leucocytoclastic vasculitis and frequent multiple organ involvement) (also see table 3). However, incomplete MC syndrome can be seen at any time during the natural history of the disease. In particular, (2) isolated serological alterations may be detected in the early stages of the disease or during clinical remission. In contrast, (3) the absence of serum cryoglobulins in patients with overt MC syndrome may be a transient phenomenon due to the wide variability in the percentage of cryoprecipitable immune complexes (IC) during the natural history of the disease or, less frequently, to switching from 'benign' B cell lymphoproliferation to malignant lymphoma.*

The most common manifestations of MC are cutaneous lesions. Orthostatic purpura is generally intermittent, with the dimensions and diffusion of purpuric lesions varying greatly from sporadic isolated petechiae to severe vasculitic lesions, often complicated by torpid ulcers of the legs and malleolar areas (figure 2). In a

significant proportion of patients, repeated episodes of purpura may lead to stable, often confluent, areas of ochraceous colouration on the legs (figure 2). Cutaneous manifestations, in particular orthostatic purpura and ulcers, are the direct consequence of vasculitic alterations with the possible contributions of various cofactors, in particular chronic venous insufficiency and physical stress, mainly prolonged standing and/or muggy weather. In addition, haemorheological disturbances due to high cryocrit levels may also be a contributing factor. In this respect, the purpuric outbreaks are often seen late in the afternoon when the highest cryocrit levels are generally found, often following prolonged standing (Ferri et al, 2002*; Ferri, 2008*).

Patients with MC frequently have arthralgias, while clear signs of arthritis (usually mild, non-erosive oligoarthritis) are less often seen.

Almost half of the patients with MC complain of mild sicca syndrome, that is, xerostomia and xerophthalmia; however, only a few cases meet the current criteria for the classification of pSS (see section 2.5).

Peripheral neuropathy may frequently complicate the clinical course of MC, in most cases as mild sensory neuritis. The common symptoms are paraesthesias with painful and/or burning sensations in the lower limbs, often with nocturnal exacerbation. The patient's quality of life may be severely compromised because of the chronicity of these symptoms together with their poor response to treatment. In a minority of cases, the peripheral neuropathy may be complicated by severe sensorimotor manifestations, which usually appear abruptly, often as asymmetric mononeuritis. In some patients, peripheral neuropathy may complicate interferon (IFN) α treatment, possibly in predisposed subjects, often during the first weeks of antiviral therapy. Central nervous system involvement, including dysarthria and hemiplegia, is rarely seen; in older patients, it is often difficult to distinguish these symptoms from the most common atherosclerotic vascular manifestations (Ferri et al, 2002*; Ferri, 2015*; Ferri, 2016*).

In over two-thirds of patients (table 3), overt chronic hepatitis, generally with a mild to moderate clinical course, can be seen throughout the natural history of the disease. This manifestation, uncommon in other systemic vasculitides, is the direct consequence of HCV infection that represents the underlying disorder in MC. In our experience, chronic hepatitis may evolve to cirrhosis in one-quarter of patients, while only seven patients (3%, 7/250; see table 3) developed hepatocellular carcinoma. In a few cases, especially in patients with renal failure due to chronic glomerulonephritis, hepatorenal syndrome develops as a major life-threatening complication. On the whole, the clinical course and prognostic value of chronic hepatitis seem to be less severe than for classic type C hepatitis without MC syndrome; similarly, hepatocellular carcinoma less often complicates MC syndrome compared with the total population of HCV-positive subjects. These differences are quite intriguing, but difficult to fully explain. It may be that patients with MC characterised by a relatively low prevalence of HCV genotype 1b, along with a lower median consumption of alcohol, develop a rather benign clinical course of liver involvement.

MPGN type 1 is another important complication, which may severely affect the prognosis and survival of patients with the disease. MC-related nephropathy is a typical IC-mediated glomerulonephritis, although other immunological mechanisms have also been hypothesised.

Widespread vasculitis involving medium to small arteries, capillaries and venules with multiple organ involvement may develop in a small proportion of patients. This extremely severe complication may involve the skin, kidney, lungs, central nervous system and gastrointestinal tract. In rare cases, intestinal vasculitis may suddenly complicate the disease, often in patients with renal and/or liver disease; pain simulating an acute abdomen is the presenting symptom of intestinal vasculitis. A timely diagnosis and aggressive treatment are necessary for this life-threatening complication.

Interstitial lung disease has been anecdotally observed in MC syndrome as well as in patients with isolated HCV infection. Almost invariably, lung involvement in MC is characterised by subclinical alveolitis, as demonstrated by bronchoalveolar lavage in an unselected patient series; this condition may predispose to pulmonary infectious complications and, in rare cases, may lead to clinically evident interstitial lung fibrosis.

The hyperviscosity syndrome due to high levels of serum cryoglobulins is another rare clinical manifestation of MC, although haemorheological alterations may contribute to some clinical symptoms such as orthostatic purpura, skin ulcers and renal involvement.

Generally, there are no associations between the severity of clinical symptoms, such as glomerulonephritis, skin ulcers and/or diffuse vasculitis, and the serum levels of cryoglobulins and/or haemolytic complement (Ferri et al, 2002*; Ferri, 2008*). Low complement activity is almost invariably detected in MC. It is characterised by a typical pattern independently of disease activity; namely, low or undetectable C4 with normal or slightly reduced C3 serum levels (table 3). Moreover, in vitro consumption of complement can also be seen owing to the anticomplement activity of some cryoimmunoglobulins. In clinical practice, it is interesting to note sudden variations in C4, rising from very low to abnormally high levels, in some patients with MC developing a B cell lymphoma. The lack of correlation between circulating cryoglobulin levels and the severity/activity of MC manifestations might be explained by different hypotheses: the pathogenic role of other non-cryoprecipitable IC, their intrinsic ability to activate the complement and/or the in situ formation of IC, with a relative concentration of HCV virions.

Some endocrinological disorders are significantly more common in patients with MC than in the general population, including thyroid disorders, diabetes and gonadal dysfunction. The most common thyroid disorders are autoimmune thyroiditis, subclinical hypothyroidism and thyroid cancer; while hyperthyroidism is less common, it may appear as a reversible complication of IFN treatment. Moreover, a significantly increased incidence of diabetes mellitus type 2 has been found in HCV-positive patients with and without MC syndrome compared with the general population. Finally, HCV-positive men with or without cryoglobulinaemic vasculitis

may develop erectile dysfunction, attributable to hormonal or neurovascular alterations, or both (Ferri et al, 2002*; Ferri, 2008*).

B cell lymphoma is the most common malignancy found, often as a late manifestation of MC syndrome. This complication may be related to peripheral B lymphocyte expansion and to lymphoid infiltrates found in the liver and bone marrow, which represent the pathological substrate of the disease. In particular, these infiltrates have been regarded by some authors as 'early lymphomas', since they are sustained by lymphoid components indistinguishable from those of B cell chronic lymphocytic leukaemia/small lymphocytic lymphoma (B-CLL) and immunocytoma. However, unlike frank malignant lymphomas, they tend to remain unmodified for years or even decades and are followed by overt lymphoid tumours in approximately 10% of cases. These characteristics justify the proposed term 'monotypic lymphoproliferative disorder of undetermined significance (MLDUS)'. Interestingly enough, the incidence of type II MC-related MLDUS is highest in those geographical areas where about 30% of patients with 'idiopathic' B cell lymphomas also display HCV positivity and where an increased prevalence of HCV genotype 2a/c has been found in both MC and lymphomas (figure 4). Type II MC-associated MLDUS presents two main pathological patterns, namely, the B-CLL-like and the immunocytoma-like. In clinical practice, malignant B cell lymphomas are often seen in patients with MC with a mild clinical course, sometimes unexpectedly during a routine evaluation. It is possible to observe a sudden decrease or disappearance of serum cryoglobulins and RF, sometimes associated with abnormally high levels of C4 as the presenting symptom of complicating B cell malignancy (Ferri et al, 2002*; Ferri, 2008*).

Other neoplastic manifestations, for example, hepatocellular carcinoma or papillary thyroid cancer, are less often seen. Thus, MC can be regarded as a pre-neoplastic disorder; consequently, careful clinical monitoring is recommended, even in the presence of mild MC syndrome.

2.4 Diagnosis

To date there are no available diagnostic criteria for MC; in 1989 the Italian Group for the Study of Cryoglobulinaemias proposed preliminary criteria for MC classification, later revised with the inclusion of clinico-pathological and virological findings. This classification is mainly based on the serological and clinical hallmarks of the disease, namely, circulating mixed cryoglobulins, low C4 and orthostatic skin purpura. Moreover, leucocytoclastic vasculitis, involving medium and, more often, small blood vessels (arterioles, capillaries and venules) is the typical pathological finding of affected tissues. It is easily detectable by a skin biopsy of recent vasculitic lesions (within the first 24–48 h).

More recently, classification criteria for cryoglobulinaemic vasculitis have been validated by a cooperative study using a standardised methodology from a larger number of countries; these criteria may be usefully

employed in epidemiological and clinico-pathogenetic studies, as well as in therapeutic trials (Quartuccio, 2014*).

In all cases, the detection of cryoglobulins in the serum is necessary for a definite classification of MC syndrome (figure 1) and their characterisation as type II (IgG+IgM monoclonal) or type III (IgG+IgM polyclonal) mixed cryoglobulins (table 3). Unfortunately, there are no universally accepted methodologies for cryoglobulin measurement, but simple standardised indications are often sufficient for testing for cryoglobulinaemia. Cryoglobulins are characterised by high thermal instability. For a correct evaluation of serum cryoglobulins, it is necessary to avoid false-negative results due to immunoglobulin cold precipitation which also occurs at room temperature. Blood sampling for cryoglobulin detection should be carried out immediately after blood is drawn or blood should be rapidly transported to the laboratory using a thermostable device (37°C). In general, to avoid the possible loss of cryoglobulins, the first steps (blood sampling, clotting and serum separation by centrifugation) should always be carried out at 37°C. In contrast, isolated serum for cryoglobulin determination and characterisation should be managed at 4°C. The serum with cryoglobulins should be tested for reversibility of the cryoprecipitate by re-warming an aliquot at 37°C for 24 h. Cryocrit measurement is usually carried out in a serum sample stored at 4°C for 7 days. The cryocrit corresponds to the percentage of packed cryoglobulins with reference to the total serum after centrifugation at 4°C (figure 9); it should be determined on blood samples without anticoagulation to avoid false-positive results due to cryofibrinogen or heparin-precipitable proteins. Without the above relatively simple precautions, the quantities of cryoglobulins measured will be incorrect and the test may completely fail to detect cryoglobulins (Ferri et al, 2002*; Ferri, 2008*).

After isolating and washing the cryoprecipitate, the cryoglobulin components can be identified by immunoelectrophoresis or immunofixation. These analyses must be performed at 37°C to avoid precipitation and hence loss of the cryoglobulin during the procedures. More sophisticated methodologies, such as immunoblotting or two-dimensional polyacrylamide gel electrophoresis, may be used for laboratory investigations. Although the detection of serum cryoglobulins is fundamental for the diagnosis of MC, the levels of serum cryoglobulins usually do not correlate with the severity and prognosis of the disease. Very low levels of cryocrit, often difficult to quantify, can be associated with severe and/or active cryoglobulinaemic syndrome; in contrast, high cryocrit values may characterise a mild or asymptomatic disease course. In rare cases, very high cryocrit levels, possibly associated with a cryogel phenomenon, may be associated with classic hyperviscosity syndrome. A sudden decrease or disappearance of serum mixed cryoglobulins, with or without abnormally high levels of C4, should be regarded as an alarming signal of complicating B cell malignancy (Ferri et al, 2002*; Ferri et al, 2015*; Ferri, 2016*).

Figure 9 Isolation and measurement of serum cryoglobulins. Graduated glass tubes with serum samples from a cryoglobulinaemic patient at different time intervals: 0, soon after serum separation from the blood sample (at least 20 mL of whole blood); 7, after 7 days at 4°C; and centrifugation of the serum for cryocrit measurement, always at 4°C.

Box 1 summarises the clinico-serological investigations at a patient's first evaluation in order to classify the MC syndrome correctly and to identify possible overlapping disorders (figure 7) (see section 2.5) or comorbidities, or both. The prevalence of these latter, in particular atherosclerosis, may be correlated with the disease duration, and with cumulative side effects of prolonged treatments. Diagnosis and monitoring of the major MC manifestations is essential for their timely treatment, especially for life-threatening liver, renal and/or neoplastic complications.

Box 1 Clinico-diagnostic assessment of mixed cryoglobulinaemia syndrome (see also Ref. Ferri et al, 2016*)**Clinical and serological investigations at a patient's first evaluation:**

- Past clinical history, physical examination
- Chest X-ray examination, ECG, abdominal ultrasonography (US), blood chemistry and urine analysis
- Cryoglobulin detection and characterisation (see table 1)
- Rheumatoid factor, C3 and C4, antinuclear antibodies (abs), antiextractable nuclear antigen abs, antineutrophil cytoplasmic abs, antismooth muscle abs, antimitochondrial abs, antiliver/kidney microsome type 1 abs, other abs
- Virological markers: hepatitis C virus (genotyping), hepatitis B virus, others
- Evaluate possible comorbidities (cardiovascular, endocrine/metabolic, etc)
- Mixed cryoglobulinaemia (MC) classification (definite, essential, secondary)

Diagnosis and monitoring of major MC complications

- Chronic hepatitis, cirrhosis, hepatocellular carcinoma:
 - Monitoring (every 6–12 months) of alanine aminotransferase, alkaline phosphatase
 - Liver US (biopsy, CT scan)
- Glomerulonephritis:
 - Monitoring of urine analysis and serum creatinine (kidney US, biopsy)
- Peripheral neuropathy:
 - Clinical monitoring
 - Electro-neuro-physiological studies
- Skin ulcers:
 - Exclusion of vascular comorbidities (arteriovenous Doppler evaluation)
- Sicca syndrome:
 - Differential diagnosis with primary Sjögren's syndrome
- Arthritis:
 - Differential diagnosis with rheumatoid arthritis
- Thyroid involvement:
 - Hormones
 - Autoantibodies
 - Neck US
 - Fine-needle aspiration
- B cell lymphoma:
 - Clinical monitoring
 - Bone marrow/lymph node biopsies
 - Total body CT scan

2.5 Differential diagnosis

Initially, the term 'essential' referred to MC as an autonomous disease once other well-known systemic, infectious or neoplastic disorders had been ruled out by a wide clinico-serological investigation. However, in some patients a definite diagnosis may be difficult because of the clinical polymorphism of the MC. Moreover, the association of MC with HCV infection may further complicate the differential diagnosis as there is frequent clinico-pathological overlapping among different HCV-related disorders. Cryoglobulinaemic syndrome can represent a crossroads between some autoimmune diseases (AIH, Sjögren's syndrome, polyarthritis, glomerulonephritis, thyroiditis, type 2 diabetes, etc) and malignancies (B cell lymphomas, hepatocellular carcinoma) (Ferri et al, 2002*; Ferri et al, 2015*; Ferri, 2016*). We can observe in the same patient a slow

progression from mild HCV-associated hepatitis to various extrahepatic manifestations (arthralgias, sicca syndrome, Raynaud's phenomenon, RF positivity, etc) and, ultimately, to overt MC syndrome with typical clinico-serological manifestations. In a minority of patients with MC, a malignancy may develop, generally after a long follow-up period. Therefore, a careful patient evaluation is necessary for a correct diagnosis of MC syndrome, particularly to differentiate it from other RF-positive, systemic rheumatic disorders such as rheumatoid arthritis (RA) and pSS (figure 7).

Arthralgias are one of the most common symptoms, while clear signs of synovitis are quite rare. Patients may develop mild, non-erosive oligoarthritis, often sensitive to low doses of glucocorticoids with or without hydroxychloroquine. In contrast, rheumatoid-like polyarthritis is more common in patients with HCV-related hepatitis without MC syndrome. In patients with HCV-associated MC and symmetrical, erosive polyarthritis, the diagnosis of overlapping MC/RA syndrome can be suspected. In these cases, the detection of serum anticyclic citrullinated peptide antibodies, markers of classic RA, may be a useful tool for the differential diagnosis.

Sicca syndrome may be suspected in about half of the patients with MC; however, current criteria for the classification of pSS are satisfied in only a few cases. MC and pSS may share various symptoms: xerostomia and/or xerophthalmia, arthralgias, purpura, RF and serum cryoglobulins and possible complication with B cell lymphoma. However, a careful patient clinical assessment is usually sufficient for a correct diagnosis in the large majority of cases following consideration of some important findings: histopathological alterations of the salivary glands and the specific autoantibody pattern (anti-Ro/SSA-La/SSB) of pSS are rarely found in patients with MC; conversely, HCV infection, cutaneous leucocytoclastic vasculitis and visceral organ involvement (MPGN type 1, chronic hepatitis) are seldom recorded in pSS (figure 7). In view of the above considerations, it has been recently proposed that the presence of HCV infection itself should be considered an exclusion criterion for the classification of pSS. In rare cases in which the differential diagnosis is very difficult, particularly in HCV-negative patients, it might be correct to classify the disorder as an overlap syndrome. Patients with MC/pSS overlap syndrome are often characterised by a more severe clinico-prognostic evolution; they show a significantly low prevalence of anti-Ro/SSA-La/SSB together with a high prevalence of MC, hypocomplementaemia, systemic autoimmune manifestations and complicating lymphomas. In clinical practice, this particular condition might be better regarded as a vasculitic syndrome with relevant implications for patient prognosis and treatment (Ferri, 2008*; Ferri, 2015*).

Finally, AIH, the old 'lupoid' hepatitis, may be associated with HCV infection, generally in the same countries in which HCV-associated MC is more commonly found. AIH may share with MC syndrome a number of extrahepatic symptoms, including serum mixed cryoglobulins. The differential diagnosis between these two conditions may be problematic: some typical features of MC (leucocytoclastic vasculitis,

hypocomplementaemia, glomerulonephritis), as well as the presence of serum autoantibodies commonly found in AIH (antismooth muscle antibodies), should be taken into account.

2.6 Prognosis

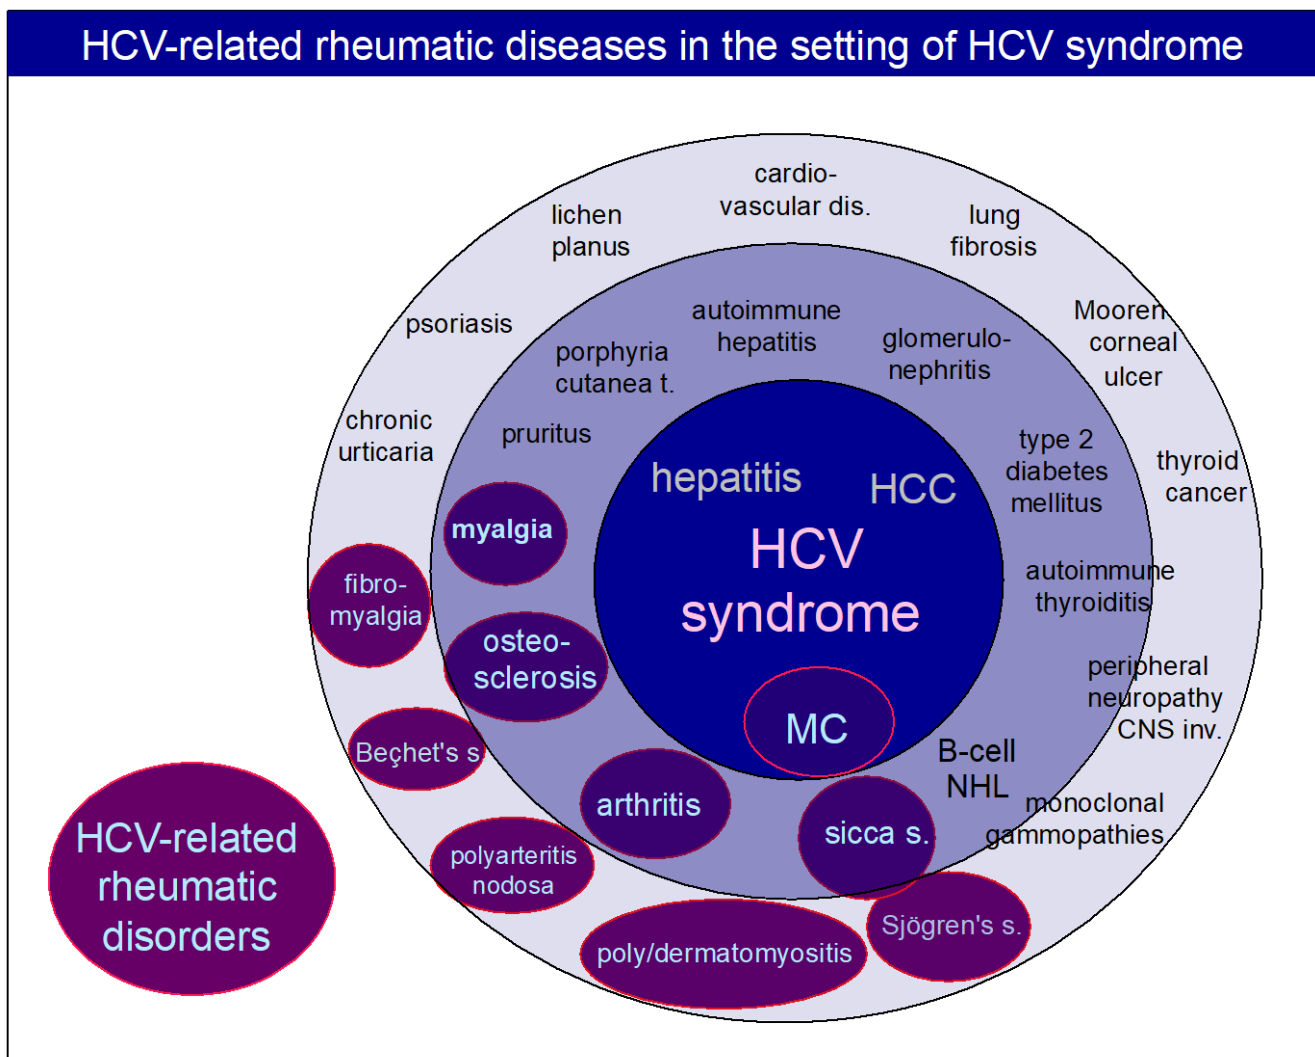

The natural history of MC is not predictable and strongly depends on concomitant diseases and complications and response to treatment. Morbidity due specifically to cryoglobulinaemia may also be significant (infections, cardiovascular diseases, progressive renal failure, advanced neuropathy). The overall prognosis is worse in patients with renal disease, liver failure, lymphoproliferative disease and malignancies. Mean survival is estimated to be about 50–60% at 10 years after diagnosis (Ferri et al, 2004*). Careful monitoring of life-threatening complications (mainly nephropathy, widespread vasculitis and B cell lymphoma or other malignancies) should be carried out in all patients with MC.

3 HCV-related extrahepatic disorders

HCV chronic infection is diffuse worldwide and may in a low but significant percentage of patients trigger a large number of extrahepatic manifestations. These include a variety of autoimmune and neoplastic disorders, among which MC is the prototypic HCV-associated extrahepatic disease (see section 2). It is a complex immunological disorder characterised by multiple organ involvement. Since MC syndrome, strongly associated with HCV infection, mimics other immune-mediated and neoplastic disorders, a possible role of HCV in these conditions has been also investigated. The spectrum of possible HCV-associated diseases includes a wide number of organ-specific and systemic diseases. Polyoligoclonal B lymphocyte expansion seems to be the common underlying alteration in a significant percentage of HCV-infected patients, some of whom may develop a variable combination of both hepatic and extrahepatic manifestations; the term ‘HCV syndrome’ refers to this complex clinical condition.

HCV-related diseases can be grouped into three different categories according to the strength of association with the viral infection based on clinico-epidemiological, histopathological and molecular biology studies (figure 10).

Figure 10 Possible clinical manifestations of hepatitis C virus (HCV) syndrome showing the strength of association between HCV and different diseases in the context of HCV syndrome. The spectrum of different HCV-associated immunological and neoplastic disorders may be classified on the basis of clinico-epidemiological, histopathological and molecular biology studies, into three different levels: (1) high: the association with HCV infection characterises the large majority of patients; HCV infection is one of the major triggering agents of the disease; (2) medium: the disease shows a significantly higher prevalence of HCV infection compared to controls; the putative pathogenetic role of HCV is also supported by pathogenetic studies and may identify at least a specific disease subset; and (3) low: the possible association is suggested by limited clinico-epidemiological observations; a pathogenetic link in at least a specific disease subset from some geographical areas is probable, but needs to be definitely demonstrated. Red circles indicate the main rheumatic diseases potentially HCV related. CNS, central nervous system; dis., disease; HCC, hepatocellular carcinoma; inv., involvement; MC, mixed cryoglobulinaemia; s., syndrome; t., tarda.

3.1 Pathogenesis of HCV-related autoimmune and lymphoproliferative disorders

The main pathogenetic insights into HCV syndrome have been provided by studies of the biological peculiarities of this virus and its possible interaction with the host immune system. In addition, studies of HCV-associated MC provided important insights into the pathogenesis of other HCV-related disorders. HCV lymphotropism is an important step in the pathogenesis of virus-related immunological disorders. A number of

epidemiological studies suggested a pathogenetic role for HCV in MC, a disorder characterised by 'benign' B lymphocyte expansion. Interestingly, the same immune-pathological alteration may also develop in a significant number of HCV-infected subjects, often in association with one or more serum autoantibodies or mixed cryoglobulins, or both.

Since HCV is a positive, single-stranded RNA virus without a DNA intermediate in its replicative cycle, viral genomic sequences cannot be integrated into the host genome. One possible hypothesis is that HCV infection exerts a chronic stimulus on the immune system, which facilitates clonal B lymphocyte expansion (Ferri et al, 2002*; Ferri et al, 2007*; Ferri, 2008*).

The t(14;18) translocation has been demonstrated in a significant percentage of peripheral blood lymphocytes from HCV-infected subjects, with consequent activation of the Bcl2 proto-oncogene (figure 6). In addition, identification of the HCV envelope protein E2, which can bind the CD81 molecule expressed on both hepatocytes and B lymphocytes, seems to be crucial for HCV-driven autoimmunity. CD81 is a cell-surface protein that, on B cells, is part of a complex with CD21, CD19 and Leu 13. This complex reduces the threshold for B cell activation by bridging antigen-specific recognition and CD21-mediated complement recognition. The interaction between HCV-E2 and CD81 might increase the frequency of VDJ rearrangement in antigen-reactive B cells. VDJ rearrangement could be responsible for the above-mentioned Bcl2 activation. The activated Bcl2 proto-oncogene can inhibit apoptosis; the consequence is an abnormally extended B cell survival. In turn, B lymphocyte expansion is responsible for the wide autoantibody production found in HCV-infected subjects, including cryo- and non-cryoprecipitable IC (figure 6). Specific autoantibodies may characterise some autoimmune disorders, while mixed cryoglobulins are the serological hallmarks of MC syndrome.

Other mechanisms such as molecular mimicry involving particular HCV antigens and host autoantigens could be responsible for B lymphocyte activation and autoantibody production (figure 6). In all cases, prolonged B cell survival can expose these cells to other genetic aberrations, which may lead in predisposed subjects to overt malignant lymphoma (figure 6). The oncogenic potential of HCV has been confirmed in patients with hepatocellular carcinoma and in a significant percentage of B cell lymphomas. Of interest, the same virus could be also involved in other malignancies such as thyroid cancer (Ferri et al, 2002*; Ferri et al, 2015*; Ferri, 2016*).

There is great geographical heterogeneity in the prevalence of HCV-related immunological or neoplastic disorders (figure 4). This epidemiological observation contrasts with the homogeneous diffusion of HCV infection worldwide. In this respect, we can hypothesise that HCV itself might be insufficient to drive the different autoimmune-lymphoproliferative disorders seen in infected subjects. The involvement of particular HCV genotypes, environmental and/or host genetic cofactors (figure 6) may contribute to the pathogenesis of

HCV syndrome. However, the actual pathogenetic relevance of the above cofactors still remains to be fully demonstrated.

It is well known that most HCV-infected subjects remain asymptomatic, some for a long time. In a small but significant percentage of patients, the virus is responsible for both hepatic and extrahepatic disorders, usually as late manifestations (figure 6). These clinico-epidemiological observations suggest that HCV syndrome is the consequence of a multifactorial and multistep pathogenetic process. It is quite common to see in the same patient a progression from mild, often isolated manifestations, to systemic manifestations and, finally, to overt malignancies (figure 6).

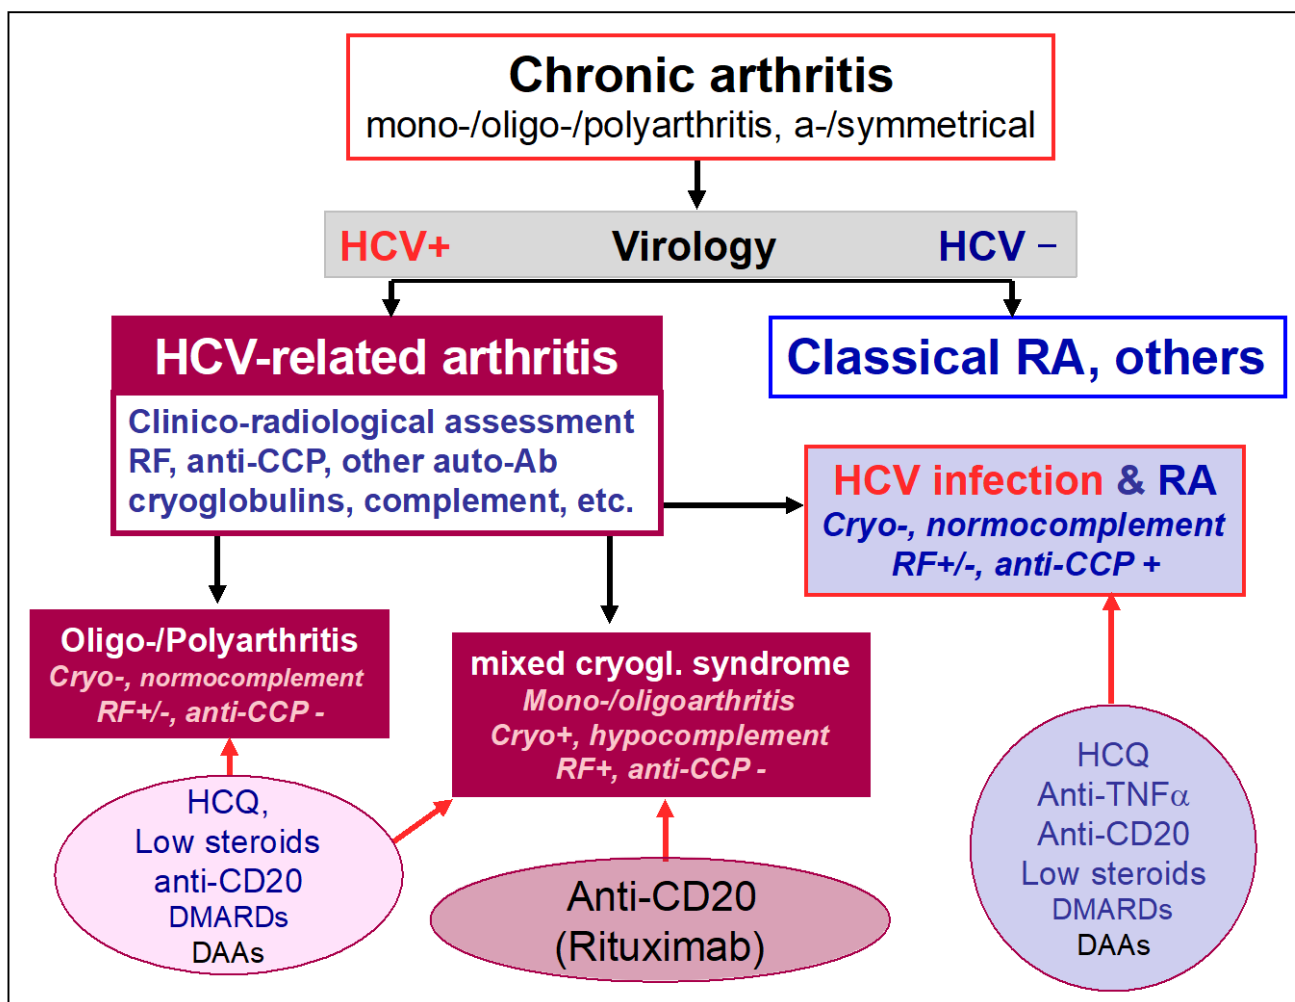

3.2 HCV and rheumatic diseases

Various inflammatory rheumatic disorders are the most common extrahepatic manifestations of HCV syndrome. Among these, MC is at the junction between classic rheumatic diseases, such as RA and Sjögren's syndrome, and other autoimmune/lymphoproliferative disorders (figures 5 and 10) (Ferri et al, 2002*; Ferri et al, 2015*; Ferri, 2016*).

Because of its clinical polymorphism, cryoglobulinaemic vasculitis may overlap with other rheumatic disorders such as Sjögren's syndrome and RA (figure 7); on the other hand, these rheumatic disorders may be occasionally associated with HCV infection (figure 7). The possible aetiopathogenetic role of HCV in pSS remains controversial. Patients with HCV-associated Sjögren's syndrome show a significantly low rate of anti-Ro/SSA-La/SSB (23%) together with a high prevalence of MC (50%), hypocomplementaemia (51%) and systemic vasculitic manifestations (58%) (figure 7). This particular condition cannot be classified as pSS; at least 50% of patients might be better classified as having cryoglobulinaemic vasculitis, which has important clinico-prognostic and therapeutic implications. The example of overlapping MC/Sjögren's syndrome suggests that in genetically predisposed subjects, HCV infection may trigger complex immune system alterations, which may produce variable phenotypes mimicking different well-known diseases, namely Sjögren's syndrome, RA, dermatopolymyositis, etc (figures 6, 7 and 10).

Chronic oligo-polyarthritis can be found in HCV-infected subjects, is often non-erosive and is barely progressive. In patients with HCV-related cryoglobulinaemic vasculitis, the joint involvement is generally characterised by mild oligoarthritis, while symmetrical rheumatoid-like polyarthritis may complicate IFN treatment in patients with type C hepatitis. Finally, given the relatively high prevalence of the two diseases, it is not uncommon to observe a simple association between classic RA and HCV infection (figure 11). Figure 7 summarises the main clinico-serological parameters for differential diagnosis between MC, pSS and RA in the setting of HCV syndrome.

Figure 11 Proposed flow chart for the classification of patients with chronic arthritis and hepatitis C virus (HCV) infection. Patients referred for either symmetrical polyarthritis or mono-oligoarthritis should undergo careful clinical and laboratory investigation, including virological evaluation. On the basis of different immunological tests, namely, rheumatoid factor (RF), anticyclic citrullinated peptides antibodies (anti-CCP), antinuclear antibodies (ANA), cryoglobulins and complement, it is possible to correctly classify anti-HCV-positive patients into two main groups: (a) those with simple association rheumatoid arthritis (RA)+HCV infection, and (b) those with HCV-related arthritis. This latter condition may include patients with arthritis in the setting of chronic HCV infection and a variable degree of liver involvement and patients with HCV-related cryoglobulinaemic syndrome. A possible therapeutic approach to different clinical subsets includes: for HCV-related arthritis, sequential treatment with antiviral agents, that is, direct-acting antiviral agents (DAAs,), and immunomodulating treatments (steroids, hydroxychloroquine (HCQ) and other disease-modifying antirheumatic drugs, rituximab) can be usefully employed (see text). In patients with concomitant HCV infection and arthritis, the use of tumour necrosis factor α blocking agents (anti-TNF α) seems to be useful and safe,. auto-Ab, autoantibodies; Cryo, cryoglobulins; DMARDs, disease modifying anti-rheumatic drugs.

Osteosclerosis is a rare condition described in adults with HCV infection; it can be defined as an acquired, painful skeletal disorder characterised by a marked increase in bone mass (figure 10). Osteosclerosis is clinically characterised by non-specific, often diffuse bony pain and tenderness over involved bones due to periosteal stretching, in the absence of joint swelling or motion limitation. The radiograph examination shows

bony sclerosis and thickening of the long-bone cortices, mainly the diaphyseal cortices. Laboratory investigations frequently reveal abnormally increased markers of bone formation (alkaline phosphatase and bone-specific alkaline phosphatase, osteocalcin); these alterations were mirrored by a marked increase in bone mass (bone mineral density, BMD) and enhanced radionuclide uptake at scintigraphy (^{99m}Tc -MDP). Bone biopsy shows an increased number and thickness of trabeculae with a parallel reduction in bone marrow. Only a very small percentage of infected patients develop osteosclerosis compared to the widespread diffusion of HCV. The pathogenesis of this rare condition is still unknown; it has been suggested that HCV alone or in combination with other unknown agent(s) may infect and alter bone cells or their precursors in predisposed subjects. These alterations might be mediated by the production of bone growth factors, such as insulin-like growth factors or osteoprotegerin. The pathogenetic role of the latter factor seems to be relevant; an imbalance in the osteoprotegerin/RANKL system leading to a predominance of osteoprotegerin has been documented.

To date, only 16 cases of HCV-associated osteosclerosis have been reported in the literature. In some cases, a partial or complete spontaneous remission of symptoms and/or bone sclerosis was observed during the follow-up period. Treatment with antiresorptive agents in some patients was ineffective, while symptomatic therapies may provide some benefit. The beneficial effect of HCV eradication observed in one patient is quite intriguing, but should be confirmed in larger numbers of patients.

The number of HCV-associated rheumatic diseases, as well as of other extrahepatic disorders, has grown during the last two decades (figure 10). In addition to the conditions described above, other rheumatic diseases have been associated with HCV infection, namely, myalgia, fibromyalgia, poly/dermatomyositis, polyarteritis nodosa, Behçet's syndrome, systemic lupus erythematosus and antiphospholipid syndrome.

In a large series of HCV-infected individuals, myalgia was mentioned by a significant number (15%) of patients. The pathogenesis of this symptom remains difficult to explain; the detection of viral genomic sequences within muscle fibres suggested a direct involvement of HCV in the pathogenesis of diffuse muscle pain. Fibromyalgia was also reported by some authors in a significant percentage of patients with chronic HCV infection, but other studies carried out in patients with typical clinical manifestations of fibromyalgia did not confirm this association. On the other hand, the differential diagnosis between fibromyalgia and muscle pain, frequently associated with weakness and arthralgias, may be very difficult in the setting of HCV-positive patients. Similarly to that proposed for sicca syndrome and pSS, some authors suggest considering HCV-associated myalgia and classic fibromyalgia as distinct entities.

The association of poly/dermatomyositis with HCV infection is described in numerous anecdotal observations, more often in patients with long-lasting viral infection or during IFN α treatment. Similarly, cases of vasculitis involving medium arteries suggesting the diagnosis of polyarteritis nodosa have been associated with HCV

infection; moreover, HCV seropositivity has been reported in a significant percentage of patients with polyarteritis nodosa. This latter association is not surprising in light of the well-known relationship between polyarteritis nodosa and another hepatotropic virus, namely HBV. Polyarteritis nodosa may share numerous clinical symptoms with cryoglobulinaemic vasculitis; thus, patients with suspected HCV-associated polyarteritis nodosa should be correctly classified by means of wide clinico-serological and pathological investigation. As regards other possible HCV-associated disorders, namely Behçet's syndrome, systemic lupus erythematosus and antiphospholipid syndrome, the data reported in the literature are generally anecdotal. Since a pathogenetic link with HCV cannot be totally excluded, the therapeutic approach in these patients is difficult (Ferri et al, 2002*; Ferri et al, 2015*; Ferri, 2016*).

As regards HCV-associated MC, patients with concomitant HCV infection and autoimmune systemic disorders, such as poly/dermatomyositis, polyarteritis nodosa and systemic lupus erythematosus, may be usefully treated with immunosuppressors (cyclophosphamide, rituximab, etc) with some important precautions and limitations due to viral infection. In all instances, a preliminary clinical evaluation of liver involvement and viral replication is necessary before any therapeutic decisions are made. The latter may be based on standard immunosuppressive treatments, possibly integrated into sequential/combined antiviral treatment.

3.3 Other HCV-related autoimmune disorders

A variety of organ- and non-organ-specific, immune-mediated diseases can be correlated with HCV infection. Cutaneous manifestations are often seen in HCV-infected subjects. Among these, porphyria cutanea tarda (PCT) is one of the most investigated. It is the commonest type of porphyria and is characterised by reduced activity of uroporphyrinogen decarboxylase, an enzyme involved in the haem biosynthetic pathway, and by frequent chronic liver disease. Since uroporphyrinogen decarboxylase deficiency is an essential condition, but not sufficient, for definite classification/diagnosis of PCT, various triggering factors, including viral infection, should be taken into account. A role of HCV infection has been investigated in several studies worldwide, which have reported a variable percentage of associations. The pathogenesis of HCV-related PCT is particularly intriguing: both metabolic factors – in particular, altered genes involved in iron metabolism – and a cross-reactivity of host versus HCV antigens have been proposed. Generally, HCV-positive patients without PCT do not show significant alteration in porphyrin metabolism; therefore, it may be supposed that a genetically driven reactivity is decisive, while HCV may exert an indirect role, possibly as a triggering factor (Ferri et al, 2002*; Ferri, 2008*; Ferri, 2015*; Ferri, 2016).

HCV-related lichen planus is another important association, in particular, oral lichen planus, which has a variable geographical prevalence. Moreover, several mucocutaneous manifestations are variably reported in HCV-infected subjects, generally based on limited or anecdotal observations. HCV-positive patients may develop acute episodes or chronic manifestations of well-known skin diseases; these symptoms are an

expression of immune-mediated cutaneous injury, triggered by HCV antigens and often amplified by IFN treatment. In many cases these cutaneous manifestations, often with a contribution from peripheral nerve alterations, severely affect patients' quality of life. Peripheral neuropathy is a common complication of HCV infection, mainly in cryoglobulinaemic vasculitis, while central nervous system involvement is less common. Peripheral neuropathy is more often seen in patients with overt MC syndrome. Vascular manifestations, including central nervous system involvement, may represent late comorbidities of HCV syndrome, particularly in patients with more severe extrahepatic manifestations and receiving long-term steroid treatment. Some cardiovascular manifestations have been reported during HCV infection, mainly in patient series from eastern Asian countries; if confirmed by further studies, they may support the role of genetic and/or environmental cofactors in the pathogenesis of HCV-related diseases.

An intriguing, still controversial, aspect is the possible aetiopathogenetic role of HCV in AIH. Patients with AIH may present serum mixed cryoglobulins, HCV infection and extrahepatic manifestations such as thyroiditis, sicca syndrome and arthritis; conversely, patients with HCV infection show one or more non-organ-specific autoantibodies and different organ involvements. In this respect, the antigenic target specificity of HCV-related autoantibodies shows only quantitative differences compared with those associated with 'primary' AIH. Again, the heterogeneous geographical distribution of HCV-associated AIH suggests a possible involvement of various pathogenetic cofactors; among these HCV might trigger a peculiar AIH clinico-serological subset which is prevalent in specific geographical areas (figure 4).

Glomerular and tubulointerstitial renal involvement in both native and transplanted kidneys may be associated with HCV infection (Ferri, 2017 review). HCV-related glomerulonephritis may include various histopathological types: MPGN with and without MC and, less frequently, membranous nephropathy, fibrillary and immunotactoid glomerulonephritis, rapidly progressive glomerulonephritis and exudative-proliferative glomerulonephritis. Cryoglobulinaemic glomerulonephritis – namely, type I MPGN – is more commonly found, while 'primary' MPGN represents less than one-third of HCV-associated MPGN. This latter disease has been described mainly in the USA and Japan. However, the real prevalence of MPGN without detectable cryoglobulinaemia is difficult to assess; it may represent a subclinical form of MC, possibly owing to difficulties and/or inadequate methods of detecting serum cryoglobulins. The possible methodological biases have been examined in section 2.4.

In some patients, MPGN is the presenting symptom of MC syndrome that may develop later in the course of the disease. Renal involvement is one of the most harmful complications of HCV-associated MC syndrome, and may severely affect the patient's clinical outcome. It is the consequence of cryoprecipitable and non-cryoprecipitable IC deposition in the glomeruli. However, the exact role of HCV in the aetiology of glomerulonephritis is not universally accepted. The presence of HCV particles in IC seems to support an indirect involvement of this virus in the pathogenesis of glomerulonephritis.

Thyroid involvement is perhaps the most common and thoroughly investigated endocrine alteration in HCV-positive patients (Ferri, 2017 review). The prevalence of abnormally high levels of antithyroid antibodies found in these patients varies markedly, ranging from 2% to 48%, with a heterogeneous geographical distribution (figure 4). These discrepancies may be correlated with variable genetic predisposition and environmental cofactors, such as iodine intake or diffusion of other infectious agents. Moreover, subclinical hypothyroidism has been found in 2–9% of patients with chronic hepatitis C, while miscellaneous thyroid alterations and raised serum thyroid autoantibodies are generally higher in chronic hepatitis C than in hepatitis B or D. More recently, the prevalence of thyroid involvement was investigated in a large series of patients with chronic hepatitis C and compared with that in control groups from the general population from regions with different iodine intake, as well as that in patients with chronic hepatitis B. Autoimmune thyroid involvement and hypothyroidism were significantly more common in patients with chronic hepatitis C than in the comparison groups, whereas the prevalence of hyperthyroidism was similar. Comparable findings were also found in another study focusing on the thyroid abnormalities of HCV-positive patients with MC (Ferri et al, 2002*; Ferri et al, 2015*; Ferri, 2016*).

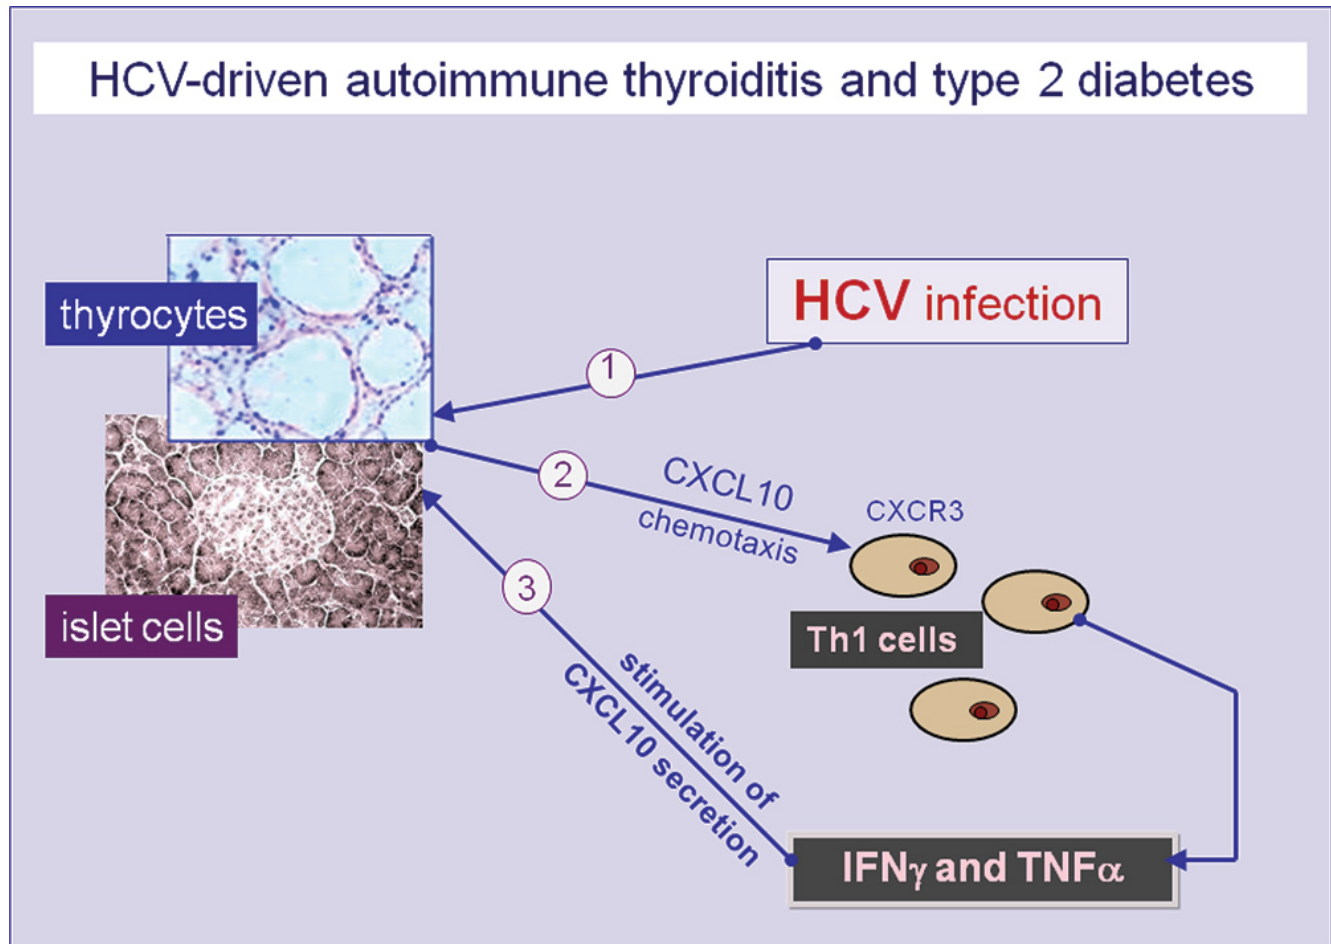

Recent studies have focused on the possible pathogenetic mechanisms responsible for HCV-related thyroid disorders. HCV thyroid infection may act by upregulating CXCL10 gene expression and secretion in thyrocytes (as previously shown in human hepatocytes) recruiting Th1 lymphocytes, which secrete IFN γ and tumour necrosis factor α (TNF- α). In turn, these cytokines may induce CXCL10 secretion by thyrocytes, thus perpetuating the immune cascade. The consequence may be the appearance of thyroid autoimmune disorders in genetically predisposed subjects (figure 12). This hypothesis has been recently confirmed by a study that evaluated CXCL10 serum levels in HCV-positive patients with MC, in the presence or absence of autoimmune thyroid involvement. Chronic immune-mediated inflammatory thyroid lesions may be responsible for the papillary thyroid cancer found in a significant percentage of HCV-infected subjects compared with controls.

Analogous pathogenetic mechanisms can be involved as a consequence of HCV infection of pancreatic β cells responsible for the upregulation of CXCL10 gene expression and secretion. The recruited Th1 lymphocytes, which secrete IFN γ and TNF- α , amplify CXCL10 secretion by β cells, thus perpetuating the immune cascade. The final result is the appearance of β cell dysfunction, with the probable contribution of genetic predisposition.

The abnormalities in thyroid function should be included among the complications of HCV syndrome. These patients should be periodically screened for thyroid involvement to identify those needing treatment and to diagnose the rare but harmful neoplastic complication at an early stage.

Type 2 diabetes may be another important manifestation of HCV syndrome, regardless of the presence and severity of liver damage.

Figure 12 Possible aetiopathogenetic mechanisms of hepatitis C virus (HCV)-related thyroid disorders and diabetes type 2. HCV thyroid infection may act by upregulating CXCL10 gene expression and secretion in thyrocytes (as previously shown in human hepatocytes) recruiting Th1 lymphocytes, which secrete interferon γ (IFN γ) and tumour necrosis factor α (TNF α). In turn, these cytokines may induce CXCL10 secretion by thyrocytes, thus perpetuating the immune cascade. The consequence may be the appearance of thyroid autoimmune disorders in genetically predisposed subjects.

Initially, clinic-based studies found an excess of type 2 diabetes in non-cirrhotic HCV-positive patients compared with patients with chronic hepatitis of other origin; however, this was not confirmed by another large study. An Italian case-control study evaluated 564 non-cirrhotic HCV-positive patients compared with 302 control subjects without a history of alcohol abuse, drug addiction or positivity for markers of viral hepatitis and 82 non-cirrhotic HBV-positive patients. A significantly high prevalence of type 2 diabetes was recorded in non-cirrhotic HCV-positive patients compared with control subjects (12.6% vs 4.9% and 7%, respectively; $p = 0.008$). Interestingly, the prevalence of type 2 diabetes in non-cirrhotic HBV-positive patients (7%) was within the range of the reported age-adjusted prevalence rates for the Italian population (4%).

A comparison between the clinical phenotype of hepatic and diabetic patients showed that non-cirrhotic HCV-positive type 2 diabetes was characterised by slightly older age, higher body mass index (BMI), elevated serum triglycerides, raised blood pressure levels and lower high-density lipoprotein cholesterol concentrations. Moreover, type 2 diabetic non-cirrhotic HCV-positive patients had a significantly lower BMI than type 2

diabetic control subjects and a slightly but significantly ($p < 0.05$) higher BMI than non-diabetic non-cirrhotic HCV-positive patients. Type 2 diabetes itself is characterised by older age, overweight, dyslipidaemia and higher blood pressure levels, the so-called 'metabolic syndrome' phenotype. In contrast, non-diabetic non-cirrhotic HCV-positive patients were lean and had low LDL cholesterol levels. Low LDL cholesterol levels have been correlated with HCV-induced hypo- β -lipoproteinaemia due to a binding competition between the virus and hepatic LDL receptor (Ferri, 2008*).

An immune-mediated mechanism for HCV-associated diabetes has been postulated and a similar pathogenesis might be involved in the diabetes of HCV-positive patients with MC. This hypothesis is strengthened by the finding that autoimmune phenomena in patients with type 2 diabetes are more common than previously thought. Similarly to the above-mentioned pathogenetic mechanisms involved in HCV-related thyroid disorders, we can hypothesise that HCV infection of β cells may act by upregulating CXCL10 gene expression and secretion. The recruited Th1 lymphocytes, which secrete IFN γ and TNF- α , amplify CXCL10 secretion by β cells, thus perpetuating the immune cascade. The final result is the appearance of β cell dysfunction, possibly in genetically predisposed subjects (figure 12).

Finally, sex hormone alterations have been observed in HCV-positive MC. Erectile dysfunction has been anecdotally reported in patients with HCV-related chronic hepatitis undergoing treatment with IFN α .

To investigate the possible role of HCV infection in gonadal dysfunction, 207 male patients with HCV infection (102 with cryoglobulinaemic vasculitis) were compared with 207 age-matched men, randomly selected from a series of 2010 subjects from the Italian general population previously investigated for erectile dysfunction. Exclusion criteria were patients aged >55 years, IFN α treatment during the past 12 months, and the presence of diabetes, renal failure, hypothyroidism, and cardiovascular and psychiatric disorders. Erectile dysfunction was significantly more common in HCV-infected subjects than in control subjects ($p < 0.001$). Sex hormone determinations showed that total and free testosterone plasma levels were abnormally reduced in HCV-positive patients with erectile dysfunction. Neither erectile dysfunction nor low levels of total and free testosterone were related to the severity of liver damage. These sex hormone alterations along with the possible contribution of peripheral neuropathy may be responsible for erectile dysfunction, which should be confirmed by further investigations. The above findings further support the role of the host hormonal environment in the pathogenesis of HCV-driven autoimmune disorders. We can hypothesise that reduced endogenous immunosuppressive activity due to low levels of adrenal-gonadal androgens may amplify the autoreactive lymphocyte proliferation triggered by HCV infection.

3.4 HCV and malignancies

HCV infection is the major aetiological factor in hepatocellular carcinoma. The oncogenic role of the virus in hepatocellular carcinoma has been definitely established. Since 1993, a possible role of this virus in the

pathogenesis of malignant B cell neoplasias has also been suggested. This hypothesis was initially suspected because of the striking association between HCV and MC, a condition that may be complicated by B cell lymphomas, and was further reinforced by the demonstration of HCV lymphotropism. In 1994, a surprisingly high prevalence of HCV infection in unselected Italian patients with B cell non-Hodgkin's lymphoma (B-NHL) was first reported. After this initial observation, an increasing number of epidemiological and laboratory investigations in patient series from different countries, as well as in animal models, confirmed the aetiopathogenetic role of HCV in a significant percentage of patients with B-NHL (figure 6). As for HCV-related MC, this association has a variable geographical distribution. The HCV-induced B cell malignancies have two main variants: the lymphomas complicating HCV-positive MC and isolated HCV-positive B-NHL. B-NHL complicating MC syndrome is discussed in section 3.3 (Ferri, 2015*; Ferri, 2016).

A significantly high prevalence of thyroid cancer complicating HCV-related hepatitis and HCV-related MC compared with controls was first noted in 1999. These data were subsequently confirmed in a case–control study, which reported a high prevalence of HCV in patients undergoing surgery for papillary thyroid cancer. Overall, HCV infection was associated with a high risk for liver cancer, multiple myeloma, B-NHL and thyroid cancer (figure 6). Furthermore, a high prevalence of thyroid cancer in subjects with a history of transfusion and/or liver disease indirectly supports the role of HCV in this malignancy. A review of the literature shows discordant results, possibly owing to important epidemiological and methodological bias. The results of a recent study on a large number of HCV-infected patients seem to confirm the high prevalence of thyroid papillary cancer, excluding the influence of some possible biases such as gender, age and iodine intake.

In our studies, features of thyroid autoimmunity were more commonly found in patients developing thyroid papillary cancer irrespective of whether they had type C hepatitis or HCV-related MC syndrome. This observation suggests that thyroid autoimmunity may be a predisposing condition for this malignancy. Although a possible association between thyroid cancer and HCV infection is suggested by the above clinico-epidemiological studies, this needs to be verified by further investigations.

3.5 HCV syndrome

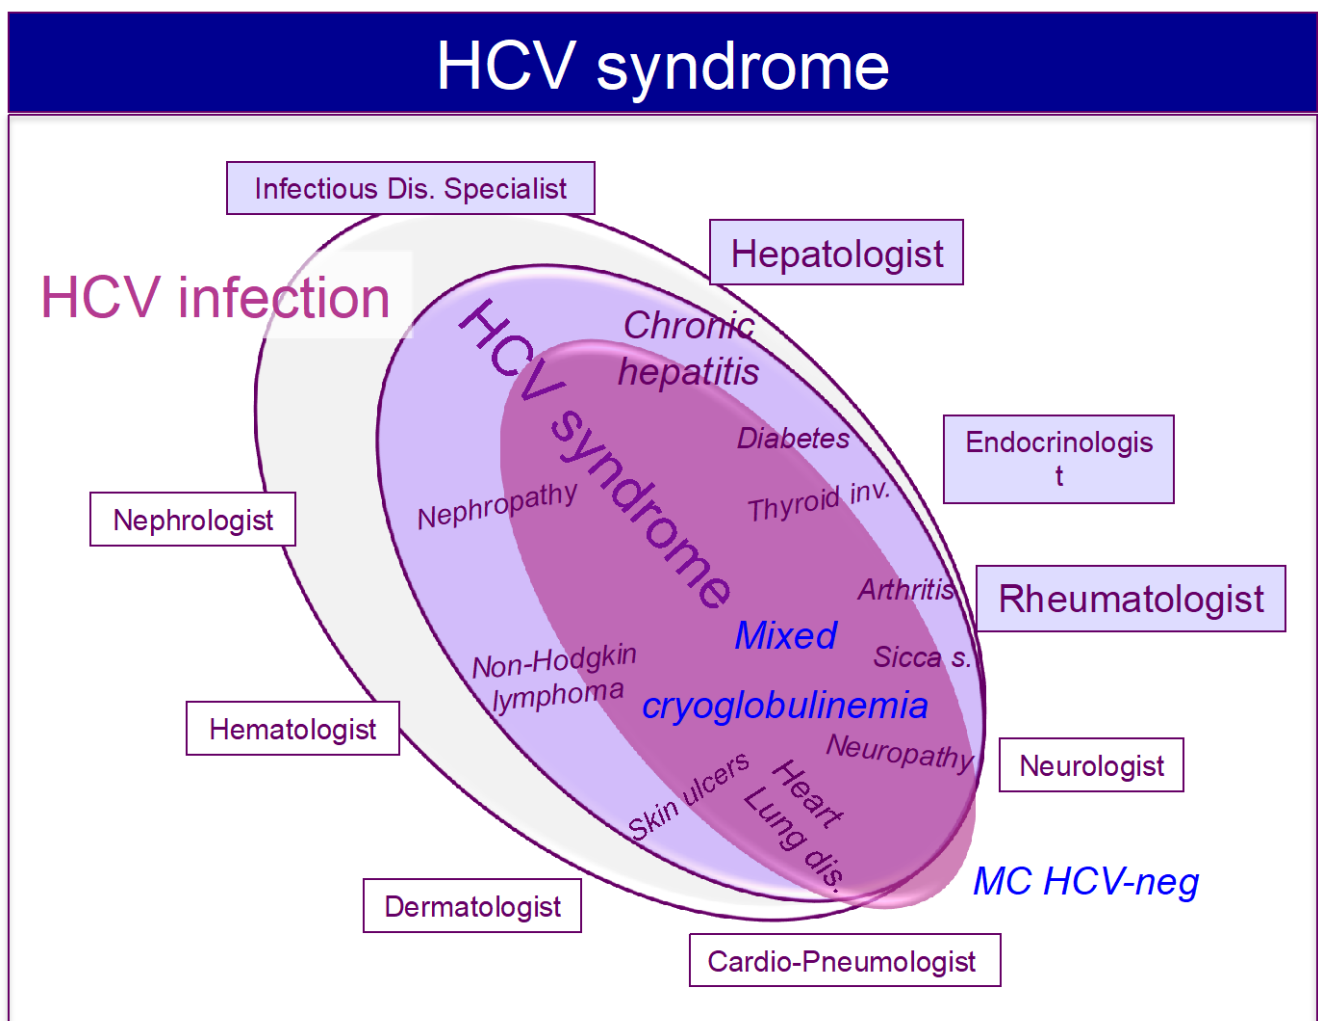

The strength of association as well as the pathogenetic role of HCV varies greatly among different diseases and for each disease among series of patients from different countries (figures 4,, 10 and 13; Ferri, 2015*; Ferri, 2016). Often, each disease itself represents a clinical syndrome which may comprise different clinico-serological subsets. These latter are the resulting phenotypes of a variable combination of different – genetic, environmental, infectious – pathogenetic cofactors. In this scenario, HCV infection, with the contribution of other pathogenetic agents, may produce distinct autoimmune or neoplastic disease subsets. The complex of HCV-related disorders is a continuum, as suggested by the clinical history of some patients, which may display the entire spectrum. It is not uncommon to see HCV-infected subjects with mild, often limited manifestations,

which may progress, generally during a long follow-up period, to more severe systemic manifestations, including malignancies (figure 6).

In general, HCV syndrome (Ferri et al, 2015*) is a multifaceted, clinico-pathological condition (figure 6 and 13); the challenge for future investigations is to better elucidate the exact boundaries of this syndrome and the actual pathogenetic role of the virus in different conditions.

Fig. 13. The HCV syndrome.

The figure schematically reproduce the spectrum of Hepatitis C virus (HCV) infection and diseases. HCV is an hepato- and lymphotropic virus responsible for a wide spectrum of both hepatic and extrahepatic diseases. The term 'HCV syndrome' refers to the multiform complex of all HCV-related diseases (Ferri, 2015*). Besides HCV-infected patients without clinical manifestations or isolated liver involvement, HCV-related extrahepatic manifestations (HCV-EHMs) may include a variety of non-organ and organ-specific autoimmune/lymphoproliferative and neoplastic disorders (Ferri, 2015*); therefore HCV-positive patients are commonly referred to different specialists according the prevalent clinical manifestation(s). Mixed cryoglobulinemia syndrome (MCs), also termed cryoglobulinemic vasculitis, represents the prototype of extra-hepatic systemic immune-mediated disorder characterized by multiple organ involvement (Ferri, 2015*). Only a minority of MC patients is HCV-negative (see also Fig. 5; Ferri, 2016*; Galli, 2017*)

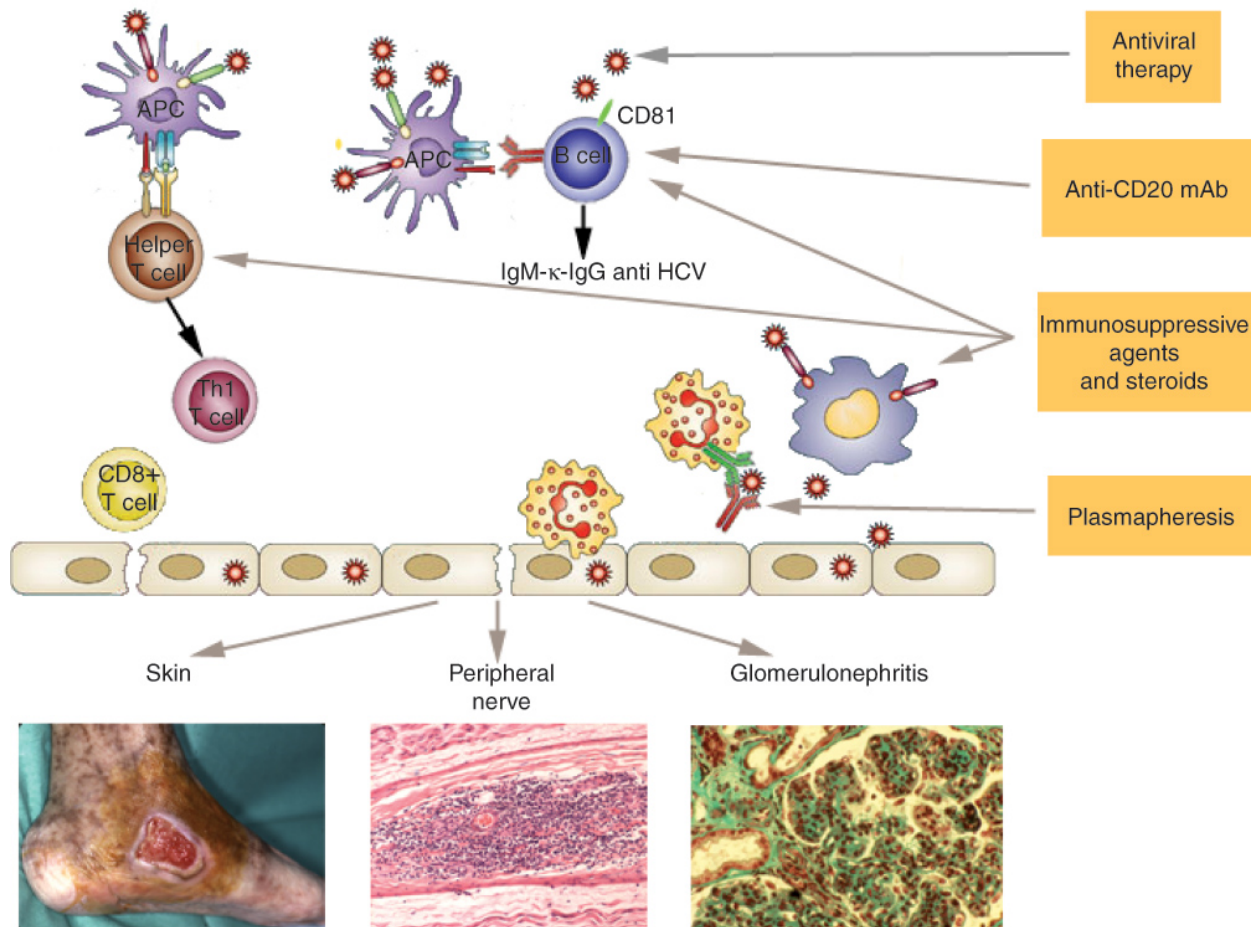

4 Current and future therapeutic strategies for treating mixed cryoglobulinaemia

Cryoglobulinemia are immune complexes that may induce systemic cryoglobulinemic vasculitis (MC), a small vessel vasculitis involving the skin, the joints, the peripheral nerve system, and the kidneys (Ferri C, 2002, 2008, 2015). With the discovery of hepatitis C virus (HCV) as the etiologic agent for most cases of cryoglobulinemia vasculitis (CV) new opportunities and problems for crafting therapy of HCV-MC have emerged. A new and major concern was the potential adverse effects that immunosuppressive therapy with glucocorticoids and cytotoxic drugs could have on an underlying chronic viral infection. Alternatively the discovery of HCV provided the opportunity to control HCV-MC with antiviral therapy (AVT) as the underlying infection drives immune complex formation and resultant vasculitis (Ferri C, 2002, 2008; Saadoun D, 2006, 2013).

Despite the successes with combination antiviral treatment, HCV-MC remains a severe disease. Most series reporting on the effects of treatment reported a mortality rate of 8-15%. The 1-year, 3-year, 5-year, and 10-year survival rates are 96%, 86%, 75%, and 63%, respectively. At the time of the diagnosis of HCV-related systemic vasculitis, severe liver fibrosis and the severity of vasculitis were the main prognostic factors (Terrier *B et al*, 2011). Although there is still controversy, the occurrence rate of B-cell NHL remains higher in MC patients compared with the general population.

The treatment of HCV and consequently the treatment of HCV-CV has evolved over the years. Figure 14 illustrates the therapeutic interventions according to the aetiopathogenesis of cryoglobulinaemic vasculitis.

Figure 14 Therapeutic interventions according to the aetiopathogenesis of cryoglobulinaemic vasculitis. mAb, monoclonal antibody.

Etiologic treatment:

- The historical treatment of HCV cryoglobulinemia vasculitis was **Interferon alpha (IFN)** in monotherapy, then in combination with **Ribavirine (RBV)**.
- Then, the treatment was based on the combination of **(Pegylated(Peg)-IFN plus RBV)**, but efficacy was limited and the side effects were frequent.
- Recently, major therapeutic advances appeared in the treatment of HCV infection, with the possibility to eradicate HCV following new **direct acting antiviral therapies (DAA)** (Gagnani L et al 2015). The first generation of HCV NS3 protease inhibitors - also known as “-previrs” - block the catalytic site of NS3, preventing the poly-protein cleavage and thus HCV replication. Currently approved “-previrs” include **Telaprevir and boceprevir** (first wave). The first generation of DAAs needed the combination of Peg-IFN and RBV and prolonged treatments.
- The second wave of previrs includes **simeprevir, paritaprevir and grazoprevir**. Two different classes of second wave DAAs have been introduced : the NS5A and the NS5B inhibitors:
 - The NS5A inhibitors block the stage of membranous genesis; they are also known as “-asvirs” (**daclatasvir, ledipasvir, ombitasvir, elbasvir, velpatasvir**).
 - The NS5B polymerase inhibitors or “-buvirs”, include nucleos(t)ide analogues (**sofosbuvir**) acting as chain terminators within the polymerase catalytic site, and non-nucleotide inhibitors (**dasabuvir**), causing conformational changes and making the polymerase ineffective.

4.1 Treatment of HCV cryoglobulinemia vasculitis

A. Antiviral agents

a) Interferon alpha (IFN) monotherapy, IFN plus Ribavirin

Treatment of HCV-MC with Interferon alpha (IFN) was associated with a relatively poor response and a high relapse rate, especially in severe cases. IFN monotherapy was effective in 50 to 100% of patients with purpuric skin lesions, but did not demonstrate efficacy on nerve or renal involvement. Combination therapy with IFN plus ribavirin showed a greater antiviral efficacy with sustained virological response in 35-80% of patients with chronic hepatitis C (Saadoun D, 2006, 2013). Such combination therapy showed much better short and long-term results in patients with HCV-MC than reported with IFN monotherapy. In three uncontrolled studies, combination therapy with standard IFN- α and ribavirin demonstrates enhanced efficacy on main HCV-related vasculitic manifestations (cutaneous, 100% ; renal, 50% ; and neural, 25-75%). Two studies reported a loss of proteinuria and haematuria in sustained viral responders treated by IFN α plus ribavirin. In a study of 27 patients with chronic hepatitis C complicated by systemic vasculitis, patients received IFN with ribavirin during 20 ± 14 months. After a mean follow-up of 57 months, 25/27 patients (93%) were alive, whereas 2 patients died secondary to cirrhosis. Most patients (75%) with a negative viraemia at the end of follow up were complete clinical responders for their HCV-MC vasculitis. Careful monitoring for adverse effects is mandatory since some manifestations of HCV-MC, such as peripheral neuropathy or skin ulcers, may worsen under IFN-based therapy. The tolerance of ribavirin is also reasonable with the exception of haemolytic anaemia requiring dosage reduction in some patients and adjusted dose in case of renal insufficiency.

b) Peg-Interferon alpha plus Ribavirin

The treatment of HCV infection (i.e. in the absence of HCV-MC) has continued to progress. It was based during the last decade on the standard of pegylated interferon alpha (Peg-IFN α) plus ribavirin leading to a sustained virological response in nearly 60% of patients (Saadoun D, 2006, 2013).

Mazzaro et al have reported the results of 18 HCV-MC patients treated with Peg-IFN α 2b plus ribavirin for 12 months. At the end of follow-up, only eight (44%) patients were still sustained clinical and virological responders. One major weakness of this study was the lower Peg-IFN dosage used in comparison with that usually recommended in HCV therapeutic guidelines.

In a monocentric study, 72 consecutive HCV-MC patients received treatment with IFN α -2b (n=32) (3 million IU x 3/week) or Peg-IFN α -2b (n=40) (1.5 μ g/kg/week), both combined with oral ribavirin (600 to 1,200 mg/day) for at least 6 months. Peg-IFN α plus ribavirin combination achieved a higher rate of complete clinical (67.5% vs 56.2%), virological (62.5% vs 53.1%) and immunological response (57.5% vs 31.2%) as compared with IFN α .

plus ribavirin, regardless of HCV genotype and viral load. Sub-group analysis of the 40 HCV-MC patients treated with Peg-IFN α plus ribavirin showed a complete recovery of skin involvement in 21/24 (87.5%), arthralgia in 18/22 (81.8%), peripheral neuropathy in 20/27 (74%) and nephropathy in 5/10 (50%) cases, respectively. Compared with standard IFN α -2b/ribavirin, there was a shorter duration of HCV therapy (13.2 vs. 18.3 months), less frequent use of corticosteroids (35 vs. 47%) and a lower rate of death (5 vs. 18.7%) with Peg-IFN α 2b/ribavirin. An early virologic response (i.e. negativation or > 2 log drop viraemia at month +3) (odds ratio [OR], 3.53; 95% CI 1.18 to 10.59) was independently associated with a complete clinical response of MC. A glomerular filtration rate lower than 70 ml/min (OR 0.18; 95% CI 0.05 to 0.67) was negatively associated with a complete clinical response of MC. Epidemiological features, viral load, transaminases or liver damage did not influence the clinical outcome of MC. The reappearance of HCV RNA was observed in 8 (11.1%) patients and 6 of them experienced a relapse of MC. In 39/70 (56%) patients, side effects included fatigue (47.2%), fever (37.5%), anaemia (33.3%), myalgia (25%), neutropenia (20%), depression (15.2%), thrombocytopenia (5%), pruritus (4.1%) and alopecia (2.7%). When compared with IFN α 2b/ribavirin, patients who received Peg-IFN α 2b/ribavirin had a similar rate of adverse events (53.1% vs 55%, respectively).

c) Direct acting antiviral drugs (DAA)

c.1) First generation DAAs: Peg-Interferon alpha plus Ribavirin and protease inhibitors

The first generation of DAAs needed the combination of Peg-IFN and RBV and prolonged treatments. Use of triple therapy with Peg-IFN α , ribavirin, and a specifically targeted antiviral agent (i.e. Boceprevir or Telaprevir) led to improve sustained virological response rates in patients infected with HCV genotype 1. In a prospective cohort study, the efficacy of an NS3 protease inhibitor (boceprevir or telaprevir [thrice daily]), in combination with Peg-IFN α 2a (180 μ g) or 2b (1.5 μ g/kg) and ribavirin (800 to 1,400 mg/day) has been evaluated in 23 HCV-MC patients with genotype 1. Thirteen patients (56.5%) were complete clinical responders, and ten (43.5%) were partial responders at week 24. The virological response (i.e. HCV RNA negativation) was of 69.6% at week 24 ($p=0.005$). The cryoglobulin level decreased from 0.44 to 0.06 g/l ($p=0.0006$) and the C4 level increased from 0.09 to 0.15 g/l ($p=0.045$). Grade 3 and 4 adverse events (mainly anaemia, neutropenia and thrombocytopenia) were observed in 10 cases (43.5%). Twenty patients (87%) received erythropoietin, 9 (39.1%) had red cell transfusion and 2 (8.7%) had granulocyte stimulating agents. Antiviral therapy discontinuation was required in 8 (34.7%) patients for virological non response ($n=5$), virological relapse ($n=2$) and depression ($n=1$). Four patients received the combination of rituximab plus Peg-IFN α /ribavirin/protease inhibitor combination with clinical improvement in all cases of whom 2 were complete clinical responders.

Recently, Saadoun et al (2015) reported the efficacy and the safety of this combined therapy in 30 CV patients, of whom 67% were complete clinical and virological responders while severe side effects occurred in 47%. Another study (Gragnani L, 2014) confirmed the good efficacy of such combination in 22 cryoglobulinemic

subjects, with a cryoglobulin disappearance in 86% but a lower sustained virological response (SVR) rate in cryoglobulinemic patients than in patients without mixed cryoglobulinemia (23.8% vs 70%, $p=0.01$). Stine et al. (2014) in a small case series of CV patients treated with triple AVT (Peg-IFN plus RBV plus sofosbuvir or first generation DAAs) suggested a longer treatment for cirrhotic patients, apparently more refractory to clear glucocorticosteroids.

c.2) Second DAAs generation:

The second DAAs generation protocols, are IFN-free (sometimes RBV free). Limited, but essentially concordant data, are available regarding patients with CV. The first study reported the effects of a sofosbuvir/RBV combination for 24 weeks in 24 CV patients; SVR was scored in 74% patients, with high rate of clinical response (87%) and low rates of serious adverse events. The rate of SVR was that expected from used AVT protocols. Sise et al. (2016), using sofosbuvir-based combinations in 12 CV subjects, obtained an improvement in renal function with or without immunosuppressant and SVR12 in 83%. An interim analysis, mostly based on the combination of paritaprevir/ritonavir, ombitasvir, plus dasabuvir, showed a cryocrit decrease and a clinical response even during treatment. The clinical improvement rate gradually increased from the inhibition of viral replication, end of treatment and SVR12. A very recent prospective study (Gragnani L, 2016) assessed efficacy and safety of sofosbuvir-based individually tailored therapy, in a cohort of 44 consecutive CV patients (median after treatment follow-up: 42 weeks, range 27–53). All patients obtained viral eradication and an overall 100% rate of clinical (complete or partial) response at week 24 post-treatment. Interestingly, a progressive increase of complete response rate over time, confirmed previous, preliminary observations. This is also suggested by another recent study conducted on 64 patients with circulating CGs (35/64 with CV) mostly treated in IFN-free regimens (Bonacci 2016). Recently, Hegazy et al. (2016) described a cohort of Egyptian and Italian CV subjects and Kondili et al. (2016) reported results of a nationwide Italian study, showing the disappearance or improvement of more than 50% of CV symptoms in 31/37 (84%) patients after DAA. Available data suggest that IFN-free AVT is safe, generally well tolerated and effective in CV patients.

B. Non-etiological treatment :

a) Rituximab:

Rituximab (RTX) binding to CD20 causes a B-lymphocytes depletion thus justifying the extensive use in B-lymphoproliferative disorders and severe autoimmune diseases. The safety and efficacy of RTX monotherapy in CV were clearly shown.

RTX is especially recommended in case of HCV related CV with severe clinical manifestations, preferring it to more conventional treatments. RTX can improve various manifestations of CV, including skin symptoms (purpura and ulcers), fatigue, arthralgias/arthritis, glomerulonephritis (GN) and peripheral neuropathy in a

relevant number of cases. It has been reported that RTX is able to restore some CV-related immune abnormalities; it can decrease cryocrit and rheumatoid factor level, increase C4 level, and induce the disappearance of bone marrow B cell clonal expansion (Saadoun, 2008).

In a literature review, 13 references reported a total number of 57 cases. Patients had a cryoglobulinemia vasculitis secondary to chronic active HCV infection in 75.4%. Most patients (48/57) received 4 weekly consecutive i.v. infusions of 375 mg/m² of rituximab. The mean follow up after rituximab infusions lasted 9.7 months (range, 3 to 24). Rituximab infusions were effective on main vasculitis signs, with a complete clinical response in 24/33 (73%). Cryoglobulinemic vasculitis relapse was noted in 13/36 (36.1%) patients within few days to nineteen months (mean 6.7 months) after the last rituximab infusion. This relapse was predictable due to the absence of viral eradication and therefore to the persistence of the viral antigenic triggering factor causing vasculitis.

In 2008, Saadoun *et al*, reported on 16 consecutive HCV-MC patients being treated with rituximab (375 mg/m² intravenously each week for 4 weeks) combined with Peg-IFN α -2b (1.5 μ g/kg/week, subcutaneously) plus ribavirin (600–1200 mg/day orally) for 12 months. Fifteen patients (93.7%) showed clinical improvement, 10 of whom (62.5%) were clinical complete responders at 12 months. Rituximab combined with Peg-IFN α 2b-ribavirin represents a safe and effective treatment option in severe refractory HCV-MC.

In 2010, Saadoun *et al* reported, 38 HCV-MC patients who received a combination of rituximab (375 mg/m²) once a week for 1 month followed by Peg-IFN (2a: 180 μ g, or 2b: 1.5 μ g/kg) weekly plus ribavirin (600–1200 mg) daily for 48 weeks. They were compared to 55 HCV-MC patients treated with Peg-IFN α /ribavirin with the same modalities. Compared with Peg-IFN α /ribavirin, patients treated with rituximab plus Peg-IFN α /ribavirin had a shorter time to clinical remission (5.4 \pm 4 vs 8.4 \pm 4.7 months; $p=0.004$), better renal response rates (80.9% vs 40% complete response; $p=0.040$) and higher rates of cryoglobulin clearance (68.4% vs 43.6%; $p=0.001$) and clonal VH1–69+ B cell suppression ($p<0.01$). Treatment was well tolerated with no worsening of viraemia under rituximab and with 11% of discontinuations due to antiviral therapy. Taken together, rituximab combined with Peg-IFN/ribavirin was well tolerated and more effective than Peg-IFN/ribavirin in HCV-MC. Rituximab synergises the immunological effect of antiviral therapy.

Dammacco *et al* reported on 22 patients with HCV-related MC who received Peg-IFN α (2a: 180 μ g, or 2b: 1.5 μ g/kg) weekly plus ribavirin (1000 or 1200 mg) daily for 48 weeks, and rituximab (375 mg/m²) once a week for 1 month followed by two 5-monthly infusions (termed PIRR) (Dammacco F, 2010). Fifteen additional patients received Peg-IFN α /ribavirin with the same modalities as the PIRR schedule. Complete response was achieved in 54.5% (12/22) and in 33.3% (5/15) of the patients who received PIRR and Peg-IFN α /ribavirin, respectively ($p<0.05$). Clearance of HCV RNA and conversion of B cell populations from oligoclonal to polyclonal in liver, bone marrow and peripheral blood was maintained for up to 3 years in 10 of 12 (83.3%) and in two of five

(40%) patients receiving PIRR and Peg-IFN α /ribavirin, respectively ($p < 0.01$). Cryoproteins in 22.7% (5/22) of patients treated with PIRR and in 33.3% (5/15) treated with Peg-IFN α /ribavirin persisted despite sustained HCV RNA clearance. No response occurred in the remaining five patients in both groups. PIRR therapy was well tolerated and more effective than the Peg-IFN α /ribavirin combination in HCV-related MC. Its effect may last for more than 3 years.

Data about combined RTX plus DAA-based therapy are still scarce. However, it is conceivable to figure out promising successes of combination with IFN-free schedules.

The exact place of RTX in the field of CV has to be more precisely defined. With the approval of recent DAAs IFN-free combination, which proved very highly and rapidly effective on viremia, we will have to define in the next future the remaining place of RTX. For example, as a first-line option for severe and life threatening conditions needing urgent intervention and as a second-line option for those maintaining significant symptoms after SVR.

Most studies used the standard haematological treatment schedule (375 mg/m² in four consecutive weekly infusions). Lower doses and/or shorter treatment have been also reported, i.e., 1g every two weeks for two infusions or 250 mg/m² in two administrations.

In most studies, tolerance of Rituximab was good. One potential concern regarding the use of such therapy reported in initial studies is its suspected propensity to worsen HCV viraemia. Some patients may experience systemic drug reactions after rituximab infusion. Six cases of HCV-MC patients who developed a severe flare of vasculitis one or two days after rituximab infusion have been reported. Two patients developed serum sickness syndrome 7 and 9 days after the first 1,000 mg rituximab infusion. Compared with patients without drug reactions, those with drug reactions had higher mixed cryoglobulin levels and more of them received 1,000 mg high-dose rituximab protocol.

b) Other treatments

Immunosuppressive agents have been given for many decades to patients with severe MC disease manifestations such as membranoproliferative glomerulonephritis, severe neuropathy and other life-threatening complication. A combination of corticosteroids and immunosuppressants, such as cyclophosphamide and azathioprine, has been used for the control of severe vasculitis lesions.

Mycophenolate mofetil may represent an alternative therapeutic option in patients refractory or intolerant to these immunosuppressive drugs. In a large retrospective study of 105 patients with renal disease associated with CV, 80% were administered corticosteroids and/or cytotoxic agents, while 67% underwent plasmapheresis. Despite this aggressive approach, long lasting remission of the renal disease was achieved in only 14% of cases, and the 10-year survival rate was only 49%.

Corticosteroids, used alone or in addition to IFN, did not favourably affect the response of HCV-CV manifestations in two controlled studies. In a randomized trial, methylprednisolone alone given for one year was associated with clinical response in 16.7% of patients, compared with 53.3% and 52.9% in patients receiving IFN α or IFN α plus methylprednisolone, respectively. GCs are commonly used to control inflammation and pain. Low-medium doses of GCs (0.1–0.5 mg/kg/day) usually control mild to moderate symptoms, whereas high-dose pulse therapy (1–10 mg/kg) is commonly indicated to manage severe and acute conditions, specifically renal failure, neurologic manifestations or hyperviscosity syndrome.

Plasmapheresis offers the advantage of removing the pathogenic cryoglobulins from the circulation of patients with MC and is particularly effective for rapidly progressive glomerulonephritis and/or severe skin necrosis or ulcers (Ferri C, 2008). Immunosuppressive therapy is usually needed associated with plasma exchange in order to avoid the rebound increase in cryoglobulin serum level seen after discontinuation of apheresis. When used in combination with HCV treatment, plasmapheresis did not modify the virologic response if IFN α was given after each plasma exchange session.

4.2 Treatment of non HCV cryoglobulinemia vasculitis

In non-HCV cryoglobulinemia vasculitis, the treatment depends of the severity of the vasculitis, of the associated aetiology (B cell lymphoma, MGUS, myeloma, Sjögren's syndrome..) and of the type of cryoglobulin (type 1 vs type 2 and 3). Low dose corticosteroids may help to control minor intermittent inflammatory signs such arthralgia or purpura, but do not succeed in cases of major organ involvement (i.e. neurologic, renal, cardiac), or in the long-term control of vasculitis. Plasmapheresis is particularly effective for rapidly progressive glomerulonephritis, life threatening organ involvement and/or severe skin necrosis or ulcers. Saadoun et al. (2012) reported the safety and efficacy of fludarabine (40 mg/m² orally on days 2–4), cyclophosphamide (250 mg/m² orally on days 2–4), and rituximab (375 mg/m² on day 1), every 4 weeks, for 3 to 6 cycles in 7 consecutive patients with severe and refractory MC associated with B-NHL. Clinical features of MC included purpura (n = 7), polyneuropathy (n =6), and kidney (n =4) and cardiac involvement (n =2). Previous treatment included rituximab (n= 5), corticosteroids (n = 5), antiviral therapy (n= 5), cyclophosphamide (n =3), and plasmapheresis (n =2). All patients achieved clinical response, with 3 (42.9%) patients achieving a complete remission and 4 (57.1%) patients a partial remission.

a) Type 1 cryoglobulinemia vasculitis

Type I cryoglobulinemia vasculitis is usually associated with plasma cell hematologic disease while MC is more likely related to low grade B cell NHL or Sjögren's syndrome. The treatment of type I cryoglobulinemia vasculitis is primarily that of the underlying haematological malignancy and the use of thalidomide or lenalidomide, and bortezomib-based regimens seem to be interesting options. In patients with MGUS-related type I cryoglobulinemia vasculitis the initiation of therapy is only justified by the severity of the vasculitis. A

recent series have reported clinic-biological characteristics and treatment of 64 patients diagnosed with type I cryoglobulinaemia. Cryoglobulinaemia was IgG in 60% and IgM in 40% of all cases and was asymptomatic in 16 patients (25%). Cold-triggered ischaemic skin manifestations were observed in 33 patients (51%). Neurological manifestations were observed in 15 patients and renal manifestations in 13. Most of the patients with necrotic purpura (14/16, $P = 0.009$) and renal manifestations (11/13, $p = 0.057$) had IgG cryoglobulinaemia. IgG cryoglobulinaemia was associated with monoclonal gammopathy of undetermined significance (MGUS), myeloma, chronic lymphocytic leukaemia and lymphoplasmocytic lymphoma in 18, 13, 5 and 2 patients, respectively. IgM cryoglobulinaemia was associated with MGUS and Waldenström macroglobulinaemia in 8 and 18 cases, respectively. One third of patients did not receive any specific treatment. Various treatments, including rituximab, were administered to 25/31 patients with IgG cryoglobulinaemia and 6/25 patients with IgM cryoglobulinaemia due to cryoglobulinaemia-related symptoms. Rituximab was ineffective in all cases associated with a predominantly plasmacytic proliferation.

b) Mixed cryoglobulinemia vasculitis

In non HCV-mixed cryoglobulinemia (MC) vasculitis, rituximab plus corticosteroids combination therapy showed the greater efficacy compared with corticosteroids alone and alkylating agents plus corticosteroids for clinical, renal, and immunologic responses and corticosteroid-sparing effect. There is no significant difference in the efficacy of rituximab therapy whether patients presented with HCV-induced or essential cryoglobulinemia vasculitis. Rituximab plus corticosteroids regimen is associated with frequent severe infections, particularly when high doses of corticosteroids are used. These infections occur in a particular subset of patients, characterized by older age, renal failure ($GFR < 60 \text{ mL/min}$), and the use of high-dose corticosteroids. The efficacy of rituximab in type I cryoglobulinemia vasculitis remains controversial. The absence of CD20 expression on plasma cells was supposed to explain its lack of efficacy.

4.3 Treatment of MC vasculitis relapses.

Clinical relapses of HCV-related vasculitis are usually associated with relapsing HCV viraemia. Vasculitis relapses usually present the same vasculitis manifestations as were noted at presentation. Recurrence of vasculitis-related symptoms after withdrawal of antiviral therapy with virological relapse (HCV RNA repositivation) can be successfully treated with another course of combination antiviral therapy with a good response. Alternatively, repeated infusions of rituximab are effective to control MC vasculitis. However, the dose, safety and continued efficacy of repeated therapy with rituximab in MC deserve further substantiation.

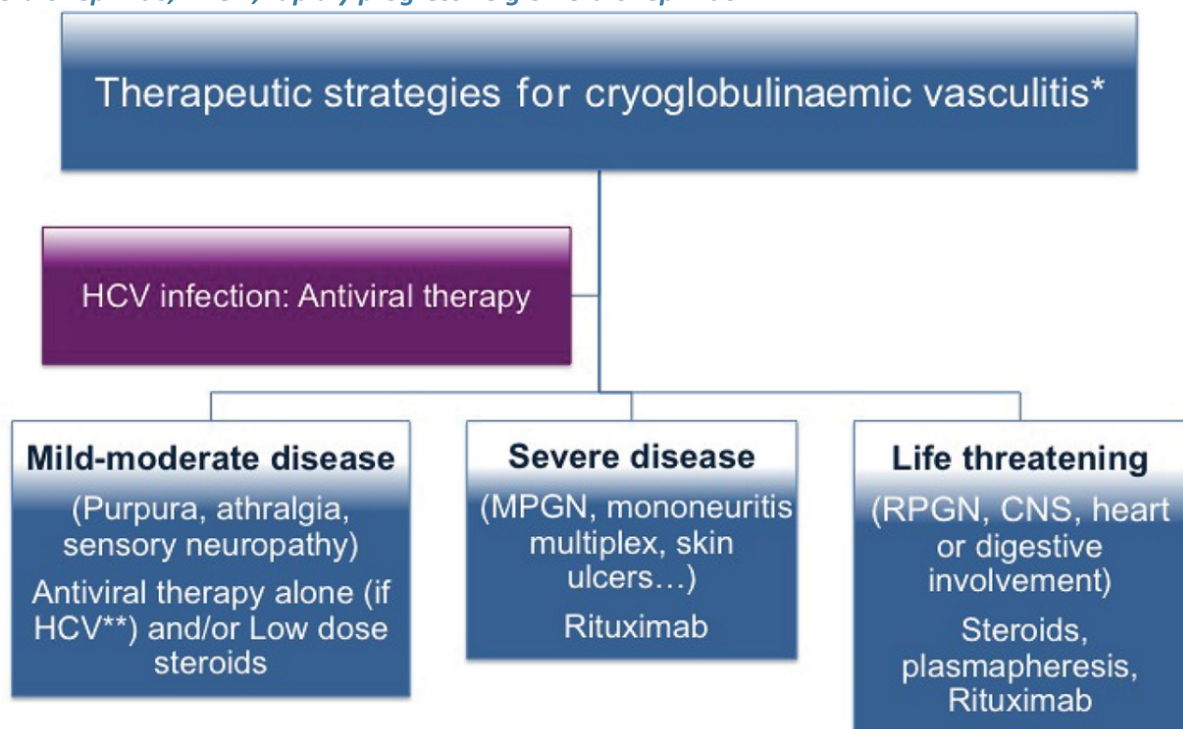

Authors have reported on 8 patients who presented with cryoglobulinemic vasculitis due to chronic active HCV infection with no evidence of underlying malignant disease. After a successful treatment of HCV infection, patients were sustained virological responders as they remained persistently HCV RNA negative. Later on, MC-related symptoms reappeared, with no HCV infection relapse (as demonstrated by numerous negative

viraemia), but a malignant B-NHL was found in two cases. Clinicians should be aware of the possibility of the presence of underlying malignant lymphoma when patients develop a relapse of cryoglobulinemia vasculitis without HCV virological relapse.

4.4 Therapeutic guidelines

The therapeutic strategies of cryoglobulinemia vasculitis are summarized in Figure 15. International therapeutic guidelines for patients with HCV-CV have been published in 2017 in the Autoimmunity Reviews (Zignego AL, 2017).

Figure 15 Therapeutic strategies in patients with cryoglobulinaemia vasculitis. **The treatment of cryoglobulinaemic vasculitis (CV) associated with haematological malignancy is primarily that of the underlying haemopathy. **If failure or contraindication of antiviral therapy or in non-HCV CV, rituximab may be used alone. CNS, central nervous system; HCV, hepatitis C virus; MPGN, membranoproliferative glomerulonephritis; RPGN, rapidly progressive glomerulonephritis.*

- Aggressive optimal antiviral therapy with new antiviral agents (DAA) should be considered as induction therapy for HCV-MC patients with mild to moderate disease severity and activity (i.e. without rapidly progressive nephritis, motor neuropathy or other life threatening complications). The duration of therapy has not yet rigorously been determined but current treatment duration in HCV-MC patients is 48 weeks for all HCV genotypes. With this strategy patients with mild or moderate disease (i.e. arthralgia, purpura, and/or sensory polyneuropathy) may be able to be managed without immunosuppressive agents. Low dose corticosteroids may also help to control minor intermittent inflammatory signs such as arthralgia or purpura.

- In patients presenting with more severe MC disease (i.e. worsening of renal function, mononeuritis multiplex, extensive skin disease including ulcers and distal necrosis), an induction phase with rituximab is often necessary. In HCV-MC, combination therapy with rituximab plus DAA is recommended as it may target both the viral trigger and the downstream B cell arm of autoimmunity. The following therapeutic schedule is recommended: 1) weekly administration of four intravenous infusions of rituximab at 375mg/m² (on days 1, 8, 15 and 22) over a one-month period; 2) antiviral combination starting after the last rituximab infusion for 3 to 6 months duration.

- For patients presenting with the fulminant forms including peripheral necrosis of extremities, rapidly progressive glomerulonephritis, digestive, cardiac, pulmonary and/or central nervous system involvement and or signs and symptoms of hyperviscosity, apheresis can have immediate beneficial effects but must be combined with immunosuppression to avoid post-apheresis rebound of MC. High dose steroids, rituximab, and sometimes cyclophosphamide combination appeared as an effective salvage treatment for refractory MC. In such cases, antiviral therapy should be started soon after the critical phase.

The treatment of cryoglobulinemia vasculitis associated with haematological malignancy is primarily that of the underlying hemopathy. When CG-related symptoms are severe, complete plasmapheresis is indicated, even though no prospective studies have established their efficacy or optimal use. The key point is to adapt treatment modalities to the nature of the underlying gammopathy. If it is plasmacytic (i.e. mainly composed of CD20 negative cells and usually secreting a mIgG), the treatment should be based on anti-myeloma agents including, in selected young patients with severe disease, autologous stem cell transplantation. If the underlying B-cell disorder is lympho-plasmacytic, usually associated with a mIgM, the treatment should be as for Waldenström's disease.

SUMMARY POINTS

- Types II and III mixed cryoglobulinaemia (MC), or cryoglobulinaemic vasculitis, are classified among the small-vessel systemic vasculitides. The disease is a combination of serological findings (mixed cryoglobulins with rheumatoid factor (RF) activity and frequent low C4) and clinico-pathological features (purpura and leukocytoclastic vasculitis with multiple organ involvement).
- There are no diagnostic criteria for MC. The disease can be correctly classified on the basis of typical orthostatic purpura with the histological pattern of leukocytoclastic vasculitis on skin samples taken within the first 24–48 h, detection of serum mixed (IgG-IgM) cryoglobulins, low complement C4 and positive RF.
- MC may be associated with other well-defined immunological, infectious or neoplastic disorders; when isolated, it is a distinct disease, the so-called 'essential' MC. Following the discovery of a striking association between MC and hepatitis C virus (HCV) infection, the term 'essential' is now used to refer to a minority of patients. In over three-quarters of cases, cryoglobulinaemic vasculitis is one of the most important extrahepatic complications of HCV chronic infection.
- The main clinical features of cryoglobulinaemic vasculitis are the typical triad of purpura, arthralgias and weakness. Liver and renal involvement, peripheral neuropathy, skin ulcers and the possible development of malignancies, mainly B cell lymphomas, generally as a late complication, may also be seen
- Liver and/or renal involvement, as well as neoplastic complications, may severely affect the overall prognosis of MC. Such patients, more often women, aged 50–60 years at the time of diagnosis, have a worse prognosis than the general population.
- HCV is both a hepatotropic and a lymphotropic virus; it may exert a chronic stimulus on the immune system with both T and B lymphocyte alterations; 'benign' B cell lymphoproliferation is responsible for different autoantibody production, mainly of RF and cryoglobulins. In addition to cryoglobulinaemic vasculitis, HCV may trigger different immune-mediated extrahepatic disorders (thyroiditis, diabetes type 2, polyarthritis, glomerulonephritis, porphyria cutanea tarda, sicca syndrome, etc.), as well as some malignancies, mainly B cell lymphomas.
- The large geographical heterogeneity in the prevalence of HCV-related extrahepatic manifestations suggests that HCV itself might be insufficient to trigger and maintain these different autoimmune-lymphoproliferative disorders. A variable combination of HCV with other unknown environmental and/or host genetic cofactors may lead to the different clinical phenotypes that characterise HCV syndrome.
- The main targets in the treatment of HCV-related cryoglobulinaemic vasculitis are the clinical (improvement of organ target manifestations), virological (clearance of HCV RNA) and immunological response (serum cryoglobulin and C4 levels).

SUMMARY POINTS

- Treatment of HCV-mixed cryoglobulinaemia (MC) may target either the viral trigger (HCV) or the downstream B cell arm of autoimmunity.
- Antiviral therapy should be considered as induction therapy for HCV-MC with mild to moderate disease severity and activity.
- IFN-free, DAA-based antiviral therapy should be considered a first line therapeutic measure for HCV-MC that does not need urgent/life threatening measures.
- In patients presenting with severe disease (ie, worsening of renal function, mononeuritis multiplex, and extensive skin disease including ulcers and distal necrosis), an immunosuppression induction phase is often necessary while awaiting the generally slow response to antiviral treatments.
- Combination therapy with rituximab and optimal antiviral treatment appears logical as it may target both the viral trigger (HCV) and cryoglobulin producing B cells.
- An early virological response to antiviral therapy is correlated with a complete clinical response in MC.
- Clinical relapses in HCV-related vasculitis are usually associated with relapsing HCV viraemia.
- Recovery of B cell count began 6–9 months after rituximab therapy.
- Low-dose corticosteroids may help to control minor intermittent inflammatory signs such as arthralgia, but are not successful in cases of major organ involvement (ie, neurological, renal) in the long-term control of vasculitis.
- Careful monitoring for adverse effects is mandatory since some manifestations of HCV-related vasculitis, such as peripheral neuropathy or skin ulcers, may worsen under IFN therapy.
- Clinicians should be aware of the possibility of malignant lymphoma when HCV-positive patients experience a relapse in cryoglobulinaemia vasculitis without HCV virological relapse.
- The treatment of cryoglobulinemia vasculitis associated with haematological malignancy is primarily that of the underlying hemopathy.

IN-DEPTH DISCUSSION I

HCV infection and arthritis

Since its discovery in the last 80s, several extrahepatic manifestations have been reported in association with hepatitis C virus (HCV), including mixed cryoglobulinemia, porphyria cutanea tarda, membranoproliferative glomerulonephritis, sicca syndrome, thyroiditis, and arthritis. Previously, the observation of a pathogenetic link between polyarteritis nodosa and HBV infection prompted an increasing interest about the possible relationship between hepatotropic viruses, liver diseases, and a variety of rheumatic disorders.

Transient articular manifestations are commonly observed during the early stages of acute hepatitis; while patients affected by chronic hepatitis, with or without cirrhosis, frequently refer arthralgias and/or frank arthritis, as well as high incidence of positive tests for rheumatoid factor (RF).

Conversely, clinical researches also uncovered a significant high frequency of hepatic alterations in some rheumatic diseases, including rheumatoid arthritis (RA). The onset of arthritis has been described in about 2-3 percent of HCV infection cases. Clinically, articular manifestations in patients with chronic HCV infection are not uniform; they include musculoskeletal pain and fatigue, fibromyalgia, arthralgias, and/or frank arthritis. While arthralgias are clinically evident in about 40–70% of patients with HCV infection, in a large prospective study of 1,614 patients with chronic HCV infection, 23% of the patients were reported to generically suffer from arthralgia and arthritis.

Several cohort studies have provided conflicting results about the impact of HCV in RA patients; despite a recent large prospective, population-based study in Taiwan, demonstrating a higher incidence of new onset RA in HCV patients, actually HCV cannot be considered as an aetiopathological agent of erosive RA. At present, this HCV-related arthritis is classified as a reactive arthritis, but a real distinction of this form from classical rheumatoid arthritis is often difficult.

In fact, chronic HCV-related polyarthritis may mimic classical RA; arthritis due to HCV infection is frequently described as "rheumatoid-like" or chronic symmetrical polyarthritis. More than 50% may satisfy the ACR criteria for RA classification. Some of the 2010 American College of Rheumatology/European League against Rheumatism criteria for classification of rheumatoid arthritis are common in HCV patients; namely arthritis of three or more joint areas, arthritis of hand joints, symmetric arthritis, alteration of acute-phase reactants, and RF seropositivity.

The clinical picture of HCV-related arthritis could be distinguished in two clinical subsets: symmetrical polyarthritis and intermittent mono-oligoarthritis.

The classical HCV-related polyarthritis usually shows a benign, often fluctuating clinical course. The vast majority of patients develop polyarticular disease, with the small joints (metacarpophalangeal, proximal interphalangeal, wrists and ankles) primarily involved. In some patients, synovitis may also affect shoulders

and knees, and large joint effusions have been described (10-30% of patients have mono- or oligoarthritis involving large joints).

Morning stiffness and positive rheumatoid factor, in 50–80% of cases, are frequent. Rheumatoid nodules are typically absent. Some authors found joint erosions in 20–30% of their subjects. In addition, the erythrocyte sedimentation rate is less commonly increased than in RA.

The oligo-monoarticular arthritis involves medium and large sized joints and rarely shows a chronic course. Symptomatic cryoglobulinaemic syndrome is closely related to this subset of HCV related arthritis. It affects the large joints of the lower limbs, where the purpuric lesions are particularly frequent; furthermore, it is generally asymmetrical, intermittent, non-erosive, and characterized by better prognosis.

These findings cannot be sufficient to formulate a correct diagnosis for individual patients; the presence of other markers of cryoglobulinaemia syndrome such as purpura, Raynaud's phenomenon, glomerulonephritis, peripheral neuropathy, and/or concomitant liver enzyme abnormalities may suggest HCV as a triggering agent of arthritis. In this respect there are some confounding features such as the normal level of liver enzymes in 1/3 of HCV-infected patients and/or the presence of cutaneous lesions that could be classified as rheumatoid vasculitis. Therefore, the search for HCV infection as well as of serum cryoglobulin and anti-cyclic citrullinated peptide antibodies (anti-CCP) should be performed in all patients with chronic arthritis at the first clinical assessment. Serum markers of classical RA may be usefully employed in discriminating HCV patients with true seropositive RA from those with HCV-related arthropathy. Some authors have pointed out the absence of anti-CCP in patients with HCV-related arthritis, while the presence of a rheumatoid factor activity may be confusing as it is positive in both classical RA and MCS.

On the whole, arthralgias and/or rheumatoid-like polyarthritis can be included among HCV-related extrahepatic manifestations. In addition, considering the prevalence of both disorders in the general population, the estimated prevalence of concomitant RA and chronic HCV infection is not negligible. On this basis it is important in clinical practice to clinically differentiate HCV-related arthritis from the simple association between classical RA and concurrent HCV infection.

Patients referred for either symmetrical polyarthritis or mono- oligoarthritis should undergo a careful clinical and laboratory workup, including virological evaluation (See figure). On the basis of different immunological tests, namely rheumatoid factor (RF), anti-cyclic citrullinated peptides antibodies anti-nuclear antibodies (ANA), cryoglobulins, and complement it is possible to correctly classify anti-HCV+ patients into: a) those with simple association RA+HCV infection; b) patients with HCV-related arthritis. This latter condition may include patients with arthritis in the setting of chronic HCV infection and variable degree of liver involvement and patients with HCV-related cryoglobulinaemic syndrome. Symmetrical RA-like polyarthritis is more commonly

found in HCV-positive patients, while HCV-related cryoglobulinaemic syndrome is rather characterized by less severe mono- oligoarthritis (Palazzi C et al. Autoimmunity Rev, 2008; 8: 48-51).

Overall, accurate patient's classification is essential for the therapeutic implications: the management of HCV-related arthritis may include both antiviral, namely interferon α (IFN α) plus ribavirin and/or new antiviral drugs, and immuno-modulating treatments (steroids, conventional or biological DMARDs).

The gold standard treatment of HCV-related arthritis has not yet been established and is largely empirical, since only a few studies have analysed this topic. The coexistence of different diseases is often considered a therapeutic challenge. Generally, treatment with hydroxychloroquine and low doses of steroids is safe and effective in controlling arthritis-related symptoms; moreover, in association with antiviral treatment. However, IFN α treatment should be avoided, owing to the potential 'arthritogenic' effect due to its immunoregulatory properties. Therefore, the eradication of HCV-infection should be considered in all patients with the new antiviral agents as a part of interferon-free eradication regimens. Due to the higher risk of comorbidities-related adverse events, and to the higher risk of developing lymphoproliferative disorders, these patients should be included among those with high treatment priority.

In refractory or severe cases, conventional or biologic DMARDs can be used, according to liver functions. Both in vitro and in vivo studies suggest that cyclosporine A (CyA) also exerts an inhibitory effect on HCV replication at standard therapeutic dose, and some reports also suggest the safety and efficacy of CyA in the treatment of patients with arthritis and concomitant HCV infection. Also methotrexate has been described efficacious and safe in a small group of HCV patients with chronic arthritis. Finally, biological DMARDs (TNF α blockers, abatacept, tocilizumab, and rituximab) have been usefully employed, alone or in combination with conventional DMARDs, in HCV infected patients.

IN-DEPTH DISCUSSION II

**Current and future therapeutic strategies for treating
mixed cryoglobulinaemia**

With the discovery of HCV as the etiologic agent for most cases of mixed cryoglobulinemia new opportunities and problems for crafting therapy of HCV MC have emerged. A new and major concern was the potential adverse effects that immunosuppressive therapy with glucocorticoids and cytotoxic drugs could have on an underlying chronic viral infection. Alternatively the discovery of HCV provided the opportunity to control HCV-MC with antiviral therapy based on the belief that the underlying infection was driving immune complex formation and resultant vasculitis. While optimum therapy is still unclear a series of recent studies suggest a role for both antiviral as well as targeted immunosuppressive therapy on autoreactive B cells in the treatment of HCV-MC depending on the activity and severity of the underlying vasculitis and the status of the underlying infection. Inducing a sustained virological and clinical response and minimizing the use of immunosuppressive drugs are the main goals in the treatment of patients with HCV-MC vasculitis.

During the last decade, several groups have reported on the efficacy of anti-CD20 monoclonal antibody (rituximab) in patients with MC. Two recent randomized studies reported the results of rituximab compared to conventional immunosuppressive therapy (glucocorticoids, cyclophosphamide, plasma exchanges or methotrexate) for MC patients in whom antiviral therapy had failed to induce remission. Remission was statistically higher in the rituximab group (83% versus 8%, $P < 0.0001$, and 64.3% versus 3.5%, $P < 0.0001$, respectively). The median duration of remission for rituximab-treated patients was 7 months, and the safety profile was good. These findings indicate that rituximab monotherapy is an effective and safe option for severe MC patients. Biologic therapy with B cell directed therapy is promising in the treatment of MC vasculitis but many questions remain regarding the appropriate position of this strategy in treatment. The duration of effect appears finite with response durations typically lasting 6-12 months and its combination with antiviral drugs is necessary. A pilot study reported the efficacy of a lower dosage of rituximab (2 infusions of 250 mg/m² instead of 4 weekly infusions of 375 mg/m²). The safety of repeated therapy in MC needs further investigation. There is no significant difference in the efficacy of rituximab therapy whether patients presented with HCV-induced or essential cryoglobulinemia vasculitis.

Based on the limitations of each therapy (i.e. antiviral and rituximab), and the 30% of MC patients that continue to have active disease while receiving rituximab or antiviral therapy, the combination of rituximab with anti-HCV therapy appeared logical. Two recent clinical trials compared the efficacy and safety profile of Peg-IFN alpha/ribavirin versus rituximab plus Peg-IFN alpha/ribavirin. Rituximab plus Peg-IFN alpha/ribavirin treated patients had a shorter time to clinical remission, better renal response rates, and higher rates of cryoglobulin clearance. Treatment was well tolerated with no worsening of viremia under rituximab. Rituximab synergized the immunological effect of antiviral therapy. In the coming years, new antiviral agents would allow eradication of HCV infection in up to 90% of cases. Recent use of triple therapy with Peg-IFN α , ribavirin, and a specifically targeted antiviral agent (i.e. Boceprevir or Telaprevir) led to significant improve sustained virological response rates and clinical remission in severe and refractory patients with HCV-MC vasculitis. New

antiviral combination (sofosbuvir based therapy), IFN-free regimens have recently proved very high virological response rate and with a very good safety profile in HCV patients. In HCV-MC patient's preliminary data are very promising. Thus, we can therefore expect a significant increase in the proportion of MC remission.

In non-HCV cryoglobulinemia vasculitis, the treatment depends of the severity of the vasculitis, of the associated aetiology (B cell lymphoma, MGUS, myeloma, Sjögren's syndrome..) and of the type of cryoglobulin (type 1 vs type 2 and 3). Low dose corticosteroids may help to control minor intermittent inflammatory signs such arthralgia or purpura, but do not succeed in cases of major organ involvement (i.e. neurologic, renal, cardiac), or in the long-term control of vasculitis. Plasmapheresis is particularly effective for rapidly progressive glomerulonephritis, life threatening organ involvement and/or severe skin necrosis or ulcers.

Type I cryoglobulinemia vasculitis is usually associated with plasma cell hematologic disease. The treatment of type I cryoglobulinemia vasculitis is primarily that of the underlying haematological malignancy. The key point is to adapt treatment modalities to the nature of the underlying gammopathy. If it is plasmacytic (i.e. mainly composed of CD20 negative cells and usually secreting a mIgG), the treatment should be based on anti-myeloma agents including, in selected young patients with severe disease, autologous stem cell transplantation. If the underlying B-cell disorder is lympho-plasmacytic, usually associated with a mIgM, the treatment should be as for Waldenström's disease.
